Continuing aspirin is considered standard if there is no clear contraindication, extrapolating from the results of the ECLAP study, which confirmed the importance of aspirin in the management of MPN.[167] Certain features may confer a patient at more risk of maternal or fetal complications during pregnancy. These include cardiovascular risk factors, prior thrombosis, and prior pregnancy-related complications that may have been caused by MPN or for which no other cause can be identified. In these settings, cytoreductive therapy or LMWH can be considered. There are no clear evidence-based management guidelines in these settings, but local practice is to use LMWH. It is clear that management of these patients requires close collaboration with a hematologist and high-risk obstetrician.

BLEEDING DISORDERS

von Willebrand Disease

Affecting approximately 1% of the population, von Willebrand disease (vWD) is the most common inherited disorder of coagulation. By mediating platelet adhesion and functioning as a carrier for circulating factor VIII, vWF plays a vital role in hemostasis. According to the most widely used classification by Sadler,[168] there are three types of vWD: type 1 (partial deficiency of vWF); type 3 (severe deficiency of vWF); and type 2, which includes four subtypes that involve qualitative defects in vWF. Factor VIIIc, vWF antigen (vWF:Ag), and the ristocetin cofactor activity (vWF:Rock) are important components of the laboratory diagnosis. vWD does not impair fertility or increase the likelihood of miscarriage.[169] Thus the management of pregnancy in patients with the condition is an important feature of the overall care for these individuals.

For pregnant women with vWD, bleeding at parturition and in the postpartum period is of primary concern. Related concerns include the administration of anesthesia, perineal hematoma, episiotomy blood loss and healing, and bleeding at surgical sites. Approximately 75% of women with moderate to severe vWD experience significant peripartum bleeding.[170] And overall, there is a 20% risk of postpartum hemorrhage in women with vWD. In a normal pregnancy, FVIIIc and vWF levels increase, beginning in the second trimester.[171] They peak as the pregnancy nears term. Among many pregnant women with vWD, particularly those with type 1 disease, a similar increase in FVIII and vWF levels is observed. Factor VIIIc levels in pregnant women with vWD peak at 29 to 32 weeks' gestation, but vWF:Ag levels peak at approximately 35 weeks' gestation.[172] The risk of peripartum bleeding is related to the level of these factors.[173] In most instances, vWF:Ag, factor VIIIc, and vWF:RCo levels should be assessed during the first and third trimesters to determine the bleeding risk for individuals with vWD. However, this may be less relevant for patients with type 3 vWD, wherein levels tend to remain low throughout pregnancy. Patients without a documented bleeding disorder who have bleeding complications during pregnancy should be evaluated for vWD because many with the disorder have a mild clinical course and remain undiagnosed for a long period.[174]

As a general rule, therapy can be rendered either in the setting of a spontaneous bleeding event or in a prophylactic context for the high-risk individual. Mainstays of therapy for pregnant women with vWD include DDAVP (1-deamino-8-D-arginine-vasopressin; desmopressin), a synthetic analogue of vasopressin, and vWF-FVIII concentrates (Humate-P, Alphanate). Cryoprecipitate can be used on an emergent basis if vWF–FVIII concentrates are unavailable but is avoided if possible during pregnancy because it poses a small risk of bloodborne infection.[175] Although antifibrinolytic therapy plays a role in the management of individuals with vWD, it is also generally avoided during pregnancy and lactation because of its potential teratogenicity and effects on newborns. Data concerning the toxicity of antifibrinolytic therapy in pregnancy are limited.

Exerting its effect through the type 2 vasopressin receptors, DDAVP rapidly and transiently increases levels of factor VIII and vWF.[176] It is administered by continuous intravenous infusion over 30 minutes in the setting of an acute bleeding event. On a prophylactic basis, it can be given subcutaneously or inhaled nasally.[177] Although highly effective when used in an appropriate clinical context, DDAVP does have limitations. Patients who have never received DDAVP therapy should be tested for responsiveness to the agent during the second trimester. Because of its potential oxytocic effect, DDAVP is pregnancy risk category B.[178] Owing to its antidiuretic effect, DDAVP can cause fluid retention and hyponatremia. Finally, DDAVP has uncertain utility in the management of women with type 2 and type 3 vWD because of an underlying genetic defect in these individuals. VWF–factor VIII concentrate is indicated for these patients.

Multidisciplinary care by an experienced obstetrician and hematologist should be provided for pregnant women with vWD. This becomes particularly important as parturition nears. In providing care for this population of patients, clinicians aim to control disease effects in the pregnant and postpartum mother. Factor VIIIc and vWF:RCo levels, PTT, type and crossmatch, and a complete blood count are obtained at the time of hospital admission. Women with vWD should be monitored for bleeding at the time of delivery, with transfusional products and DDAVP available for use as needed. vWF:RCo and factor VIIIc levels of 50 IU/dL generally serve as a target at parturition and in the postpartum period; expert opinion suggests that women with levels below this should receive replacement products.[178]

In the management of pregnant women with vWD, the provision of regional anesthesia during delivery is an important topic. Some anesthesiologists use epidural anesthesia in patients with mild disease with or without the use of DDAVP.[179,180] For patients with moderate to severe disease, an alternative form of analgesia may be considered. If epidural analgesia is used in a patient with moderate to severe disease, prophylactic therapy is indicated. The epidural catheter should be removed soon after delivery because falling factor levels in the postpartum period increase the bleeding risk.[176]

The route of delivery is also an important matter in patients with vWD. To minimize the risk of neonatal hemorrhage, some obstetricians recommend cesarean delivery for patients with type 2, type 3, and clinically moderate type 1 disease. However, neonatal bleeding occurs in the setting of cesarean delivery as well, and delivery methods have not been rigorously compared.[170,179]

Prenatal testing is a challenge in women with vWD. The specific mutations involved in the pathogenesis of type 1 and type 3 vWD are not known. And multiple mutations are involved in the pathogenesis of type 2 vWD. Fetal blood vWF levels can be obtained if necessary, but inherent risks are associated with the procedure.[181] Expectant mothers should be informed of these risks in making decisions about prenatal genetic testing.

HEMOPHILIAS

The hemophilias (A and B) are X-linked recessive diseases characterized by hemarthrosis and subcutaneous and intramuscular bleeding.[182] Hemophilia A results from deficient production of factor VIII, and hemophilia B, from deficient production of factor IX. As X-linked disorders, hemophilia A and B occur most often in men, but they can occur in women under several circumstances, including X-chromosome inactivation (lyonization), X hemizygosity, and double heterozygosity as can occur in the female offspring of an affected father and carrier mother.[182] In the United States, women account for 1.7% of patients with hemophilia A and 3.2% of patients with hemophilia B.[183] Fifty percent of male offspring from a female carrier inherit the

disorder, whereas 100% of male offspring from an affected mother inherit the disease. Female carriers in both disorders can be detected through laboratory screening and pedigree analysis.[184] Women with hemophilia and pregnant women with an affected fetus must be monitored closely during pregnancy for bleeding events that compromise the well-being of either the mother or fetus. Fetal umbilical blood sampling can be used to check factor VIII and factor IX levels. Chorionic villus sampling may also be used.[185]

At parturition, women with hemophilia A whose factor VIIIc level lies below 50% of the normal range should receive purified factor VIII. Levels should be greater than 80% for surgery and maintained at 30% to 40% for 3 to 4 days postoperatively. Rarely, thrombosis can occur in the aftermath of factor VIII replacement therapy.[186] Six to 10% of neonates with hemophilia have hemorrhagic complications in the perinatal period, including intracranial hemorrhage. Vacuum extractors, forceps delivery, and scalp electrodes should be avoided. To date, no studies have rigorously compared vaginal and cesarean delivery in this patient population. Neonatal blood should be assayed for factor VIIIc levels and PTT immediately after birth. Neonates with low factor VIIIc levels may require serial cranial ultrasounds to rule out bleeding.[187]

Hemophilia B is treated in a similar fashion. However, it should be noted that cryoprecipitate contains low levels of factor IX and should not be used as replacement therapy in the management of this condition. Purified factor IX is the agent of choice for patients with hemophilia B. Meanwhile, individuals with other clotting factor deficiencies should receive fresh frozen plasma or specific clotting factor products to maintain factor levels at greater than 25%.[188] One exception to this pertains to the management of patients with factor XIII deficiency; the occurrence of spontaneous recurrent abortions and uterine bleeding in these individuals necessitates regular infusions of fresh frozen plasma or factor XIII concentrate to maintain pregnancy.[189]

Table 153-2 Hemostatic Changes in Pregnancy

Factor XIII	↑/↓
Protein C, antithrombin	=
Protein S	↓
Factor XI	↓/ =
Factors V, VII, VIII, IX, X, XII	↑
von Willebrand factor, fibrinogen	↑
Tissue plasminogen activator	↓
Prothrombin, D-dimer	↑

Bleeding Associated With Factor XI Deficiency

A 25-year-old female is referred for prolonged PTT discovered during pregnancy. Evaluation reveals severe factor XI deficiency. She has no history of easy bruising or bleeding. She is at 30 weeks' gestation and is here for evaluation prior to delivery.

Bleeding associated with factor XI deficiency can be quite variable, ranging from no bleeding symptoms to bleeding associated with trauma or surgery. For a patient without a history of bleeding, prophylaxis is not necessary but fresh frozen plasma should be available if needed. Epidural is usually contraindicated in patients with severe factor XI deficiency, and women should be advised to speak with the treating anesthesiologist prior to delivery in order to plan alternative strategies. If consideration for regional block anesthesia is made, it is usually administered with FFP prior and with documentation of normalization of the PTT.

In patients with a bleeding history, FFP should be administered prior to delivery, as well as 2 to 3 days later to reduce the risk of delayed hemorrhage.

VENOUS THROMBOEMBOLIC DISEASE AND PREGNANCY

Venous thromboembolic (VTE) disease is a leading cause of maternal morbidity and mortality.[189] The risk of VTE increases two- to fourfold during pregnancy and the early postpartum period.[190] In women who have had a previous VTE event, pregnancy appears to increase the risk of a recurrent thromboembolic event.[191] Various factors account for the prothrombotic state associated with pregnancy. Increased estrogen levels early in pregnancy increase venous distention and contribute to venous stasis.[192] Increased plasma volume and compression of the inferior vena cava by the gravid uterus contribute to venous stasis as well.[193] In addition, studies have demonstrated decreased blood flow velocity in pregnant women, particularly in the left leg when pregnant women lie in a supine position. This phenomenon likely explains the increased risk of left leg thrombosis among pregnant women.[194] Furthermore, whereas the concentration of coagulation factors changes during pregnancy, the concentration of vWF, fibrinogen, and prothrombin, along with factors V, VII, VIII, IX, X, and XII increases, and the concentration of factor XI and protein S decreases (Table 153-2).[195–197] Finally, fibrinolytic activity decreases during pregnancy as the levels of plasminogen activator inhibitors 1 and 2 increase.[198] Other factors—including high body mass index, smoking, immobilization, and age older than 35 years—should also be considered when assessing the thrombotic risk of a pregnant woman (see box on Bleeding Associated With Factor XI Deficiency).

Because of the prothrombotic physiology associated with pregnancy, a clinician's concern for VTE in a pregnant woman should prompt immediate evaluation. To assess for lower extremity thrombosis, venous compression ultrasonography remains the initial test of choice. Ultrasonography poses no threat to the fetus and can detect thrombosis of the proximal common femoral and popliteal veins with a sensitivity of 95% and specificity of 96%. Despite the efficacy of ultrasonography, limitations to its use do exist. The test is less effective for the diagnosis of calf vein thrombosis, with a sensitivity and specificity in the 60% to 70% range.[199] For this reason, a woman with suspected lower extremity deep venous thrombosis should undergo serial ultrasonography if the initial evaluation is nondiagnostic.[200] Similarly, thrombus in the common iliac vein can evade diagnosis by venous compression ultrasonography.

In such cases, other modalities such as contrast venography and magnetic resonance venography (MRV) can be considered. Although contrast venography exposes the fetus to radiation and should thus be used with caution during pregnancy, its use may be warranted when clinical suspicion for an underlying thrombotic event is high.[199] Serum D-dimer tests are often used in conjunction with imaging studies to assess for thrombosis in nonpregnant patients. The sensitivity of D-dimer tests for the presence of thrombus ranges from 85% to 95%.[201] However, several pregnancy-associated conditions elevate D-dimer levels, including preterm labor, placental abruption, and hypertension of pregnancy, thus undermining the utility of the test somewhat in pregnant women by decreasing its specificity.[198] Nonetheless, when normal, the D-dimer assay provides the clinician with useful information.

When lower extremity imaging reveals no evidence of thrombus in a pregnant woman with suspected pulmonary embolism (PE), the clinician has several options. Helical CT has become the standard modality for the diagnosis of PE in nonpregnant individuals at many centers. However, even with abdominal shielding, the procedure results in fetal radiation exposure (≈16 mrad) because of internal scatter.[202] Although this low level of radiation exposure probably does not cause harm to the fetus, repeated imaging during the course of pregnancy is to be avoided.[200] Ventilation/perfusion (V/Q) scanning is frequently used in the evaluation of pregnant women with suspected PE but has limitations as well. Results of a prospective study indicate that when used in this patient population, V/Q scanning

infrequently yields a conclusively positive result (1.8% of cases) and is often nondiagnostic (24.8% of cases).[203] Finally, pulmonary angiography can be used in the evaluation of PE in rare instances when the previously described diagnostic tests yield nondiagnostic results in the face of a high clinical suspicion.

Venous thromboembolism in pregnancy is treated with heparin. Until LMWH was introduced in the late 1980s, unfractionated heparin (UFH) was the anticoagulant of choice for treatment of pregnant women with VTE. Because it does not cross the placenta, UFH is nonteratogenic. However, drawbacks to UFH therapy, including heparin-associated osteoporosis, heparin-induced thrombocytopenia (HIT), and the drug's unpredictable pharmacokinetics, are well documented.[189] Heparin-associated osteoporosis can develop in women who receive at least 1 month of therapy; it is likely related to a toxic effect of heparin on osteoblasts.[204] Because of its more favorable side effect profile, reliable pharmacokinetics, and equal efficacy in treating VTE, LMWH now represents the most commonly used anticoagulant for treatment of VTE in pregnancy.[205] The risk of osteoporosis and HIT appears to be less with LMWH-based anticoagulation than with UFH-based anticoagulation.[206,207] Although practice patterns vary, it is reasonable to base the initial dose of LMWH on early pregnancy—rather than current—weight.[207] Because clearance of LMWH increases during pregnancy, twice-daily dosing regimens are preferred to once-daily regimens.[208] In terms of duration of therapeutic anticoagulation, many clinicians continue therapy at full dose through the entire pregnancy and puerperium based on the rationale that pregnancy itself represents a risk factor for recurrent VTE.[205] In contrast, other clinicians advocate initial anticoagulation with full-dose LMWH for a designated period followed by conversion to an intermediate dose. This approach may be beneficial for individuals susceptible to side effects of anticoagulation such as bleeding or osteoporosis.[189] The risk of significant bleeding with LMWH during pregnancy is estimated to be around 2%.

Warfarin is contraindicated in pregnant women. It crosses the placenta and can cause both fetal hemorrhage and nervous system abnormalities and other teratogenic effects.[209] Warfarin can be used in the postpartum period after initiating therapy with concurrent heparin and in this setting does not appear to increase the risk of bleeding in children of lactating mothers.[199]

Anticoagulation should be discontinued at the time of parturition. UFH and LMWH should, in most circumstances, be stopped 12 to 24 hours before delivery. If the risk of recurrent VTE is particularly high in a woman receiving LMWH, the clinician can convert to intravenous UFH and treat until 4 to 6 hours before delivery, minimizing the time off anticoagulation.

The risks of regional anesthesia must be weighed carefully in women receiving anticoagulation because therapy increases the likelihood of bleeding, hematoma formation, and potential neurologic compromise. In a woman undergoing elective delivery with discontinuation of anticoagulation 12 to 24 hours prior, epidural anesthesia may be used. UFH or LMWH may be reinitiated 6 to 12 hours after delivery or after removal of the epidural catheter. Then, after therapeutic levels of UFH or LMWH have been achieved, warfarin may be initiated.

PROPHYLACTIC ANTICOAGULATION DURING PREGNANCY

Given the prothrombotic state associated with pregnancy itself, prophylactic anticoagulation should be considered in pregnant women with a history of VTE. Recurrence rates for VTE during pregnancy may be as high as 12% based on the results of retrospective studies.[210] Conversely, Brill-Edwards and colleagues[211] prospectively studied 125 pregnant women with prior VTE in a study that excluded women with known thrombophilia. Study subjects did not receive prophylactic anticoagulation during the antenatal period, but did receive anticoagulation therapy for 4 to 6 weeks postpartum. The authors documented a VTE recurrence rate of 2.4%. Women who had a temporary risk factor at the time of their initial VTE event and lacked laboratory evidence of an underlying hypercoagulable disorder at the time of study enrollment experienced no recurrences during pregnancy. Based on the results of this study, routine prophylactic anticoagulation for women with a single previous VTE event is not recommended. However, patients with a known hypercoagulable state, those with multiple previous VTE events, and those considered high risk for recurrent VTE should receive prophylactic anticoagulation during pregnancy and for 4 to 6 weeks postpartum. As previously discussed, prophylactic anticoagulation can be discontinued at parturition and reinitiated 6 to 12 hours postpartum.

The management of pregnant women with prosthetic heart valves is controversial and deserves special attention, although a full review of the topic is beyond the scope of this review. Coupled with the prothrombotic physiology of pregnancy, the presence of a prosthetic valve places such women in an ultra-high risk category. Before the introduction of LMWH, options for anticoagulation in this patient population included (1) warfarin throughout pregnancy, (2) warfarin with UFH during weeks 6 to 12, the period of major organogenesis, and (3) UFH throughout pregnancy.[189] More recently, LMWH has been used in this setting, although its safety and efficacy have been questioned on the basis of several studies. Overall, a lack of rigorous, comparative studies hinders evidence-based management of women with prosthetic heart valves. Current recommendations allow for one of three therapeutic strategies, initiated after a thorough discussion of risks and benefits with the patient: (1) warfarin, with LMWH or UFH substituted during weeks 6 to 12, (2) dose-adjusted UFH throughout pregnancy, or (3) dose-adjusted LMWH throughout pregnancy.[189]

THROMBOPHILIA AND PREGNANCY

Thrombophilias, inherited and acquired, increase the risk of VTE in pregnant women and adversely affect pregnancy outcomes. Included within this category of diseases are factor V Leiden, prothrombin gene polymorphisms, antiphospholipid antibody syndrome, antithrombin deficiency, and protein S and C deficiency. In addition, hyperhomocysteinemia and methylenetetrahydrofolate reductase C677T mutation have been studied. There are varied results when assessing the literature in regards to the risk of pregnancy-associated VTE in the setting of an inherited thrombophilia. A meta-analysis in 2005 reviewed the risk of VTE during pregnancy by the specific thrombophilia present. The inherited thrombophilias (with the exception of *MTHFR* mutation) were associated with a statistically significant increase in the risk of VTE during pregnancy.[212] But because the overall incidence of VTE in pregnancy is low, in women without a history of thrombosis, the absolute risk conferred by thrombophilias is generally low. The positive predictive value of factor V Leiden heterozygosity was one in 500. Prothrombin heterozygosity was one in 200. Women with homozygosity for these mutations, double heterozygosity and antithrombin III deficiency were at highest risk. Given the increased risk of VTE in those particular settings, aggressive management with prophylactic anticoagulation is warranted.

Screening for inherited thrombophilia in patients with recurrent miscarriage or pregnancy complications such as preeclampsia or placental abruption is not indicated. Thrombophilia screening is only indicated in patients with a prior thromboembolic event or a high likelihood of thrombophilia. Selective screening based on personal and family history is recommended (see box on Thrombophilia During Pregnancy).

Prophylactic treatment of carriers of low-risk mutations with any personal or family history of VTE is not indicated. In patients with recurrent miscarriage, anticoagulation has been used in efforts to improve rates of live birth. There have been varied results in clinical trials using anticoagulation in the setting of recurrent miscarriage. However, in the large, multicenter, randomized, placebo-controlled study examining the use of aspirin or aspirin plus heparin in women with unexplained miscarriage, there was no improvement in the live birth rate compared with placebo.[213]

Thrombophilia During Pregnancy

A 25-year-old female wishes to become pregnant. Her mother suffered from a PE at the age of 60, underwent thrombophilia evaluation, and was found to be heterozygous for the factor V Leiden mutation. She herself has never suffered thrombotic episode, just recently discontinued her birth control, and was told to see a hematologist before she became pregnant. Her primary care physician tested her for Factor V Leiden and she is heterozygous for the mutation. She is asking if she should be on anticoagulation during her pregnancy.

Every case of thrombophilia during pregnancy needs to be assessed on a case by case basis. Asymptomatic women who harbor thrombophilic conditions, but have never manifested clinical manifestations, do not require anticoagulation. In women with a personal history of thrombosis an inherited thrombophilia, anticoagulation during and in the postpartum setting should be used.

Table 153-3 Antiphospholipid Antibody Syndrome

Vascular Thrombosis
One or more episodes of arterial or venous thrombosis confirmed by imaging
Pregnancy Morbidity
Death of a fetus beyond 10 weeks' gestation with normal fetal morphology
Premature birth before 34 weeks' gestation
Three or more consecutive spontaneous abortions before 10 weeks' gestation
Laboratory Criteria (All Measured on Two or More Occasions at Least 12 Weeks Apart)
Lupus anticoagulant on two or more occasions at least 12 weeks apart
Anticardiolipin antibody
Anti-B2 glycoprotein IgM or IgG

Ig, Immunoglobulin.

Antiphospholipid Antibody Syndrome

The antiphospholipid antibody syndrome (Table 153-3) is the most common form of acquired thrombophilia.[214] Antiphospholipid antibodies include lupus anticoagulant antibodies and anticardiolipin antibodies. They can occur as a manifestation of various conditions, such as systemic lupus erythematosus (SLE) and other rheumatic diseases, infection, and drug reactions. Antiphospholipid antibodies exert their prothrombotic effect through several mechanisms. For example, they inhibit the activity of anticoagulants thrombomodulin, protein S, protein C, β2-glycoprotein I, and prostacyclin.[215-217] They interact with phospholipids on the surface of platelets, increasing platelet adhesiveness and production of von Willebrand mulitmers.[218,219] And in pregnant patients, antiphospholipid antibodies decrease levels of annexin V, a potent vascular endothelial anticoagulant produced by placental trophoblasts.[220] Nonpregnant individuals with antiphospholipid antibody syndrome can develop arterial and venous thromboses. In pregnant women, antiphospholipid antibody syndrome can manifest as thrombotic events, spontaneous abortion, preeclampsia, and HELLP syndrome, as well as IUGR.[221-224]

Antiphospholipid antibodies can be detected in 5% of healthy pregnant women and 37% of pregnant women with SLE.[225] Thrombotic events occur in approximately 5% of pregnant women with antiphospholipid antibodies.[224] All pregnant women with SLE should undergo testing for antiphospholipid antibodies. Women who sustain recurrent spontaneous abortions or a thromboembolic event during pregnancy should also undergo evaluation for the disorder. A history of either vascular thrombosis or fetal loss coupled with the presence of either lupus anticoagulant antibodies or anticardiolipin antibodies establishes the diagnosis of antiphospholipid antibody syndrome.[226]

False-negative laboratory results do occur and do so more frequently in pregnant than in nonpregnant women. This may be because of the increased concentration of clotting factors observed in pregnancy.[227] Women with antiphospholipid antibody syndrome who have sustained prior thrombotic events receive therapeutic anticoagulation during pregnancy. Those with antiphospholipid antibodies but no manifestations of the clinical syndrome should receive prophylactic anticoagulation.

FUTURE DIRECTIONS

Managing of the hematologic complications of pregnancy continue to be a challenge. The physicians and patient involved all benefit from a multidisciplinary approach. In certain disorders, the management is clear and will likely remain unchanged in the future. In other disorders, treatment paradigms may shift as new treatments are discovered for the nonpregnant patient. In all instances, further well-designed studies will continue to advance evidence-based management of the pregnant patient.

CHAPTER 154

HEMATOLOGIC MANIFESTATIONS OF CHILDHOOD ILLNESS

Arthur Kim Ritchey, Frank G. Keller, and Sarah H. O'Brien

The hematologic response to systemic illness in children is similar to that in adults. A number of disorders occur more frequently in children, however, and some are unique to the pediatric population. In addition, interpretation of the hematologic response is predicated on knowledge of the normal developmental changes that occur within the hematopoietic system throughout childhood (Table 154-1). This chapter focuses on the hematologic manifestations of common or unique systemic diseases that occur in neonates, children, and adolescents. Illnesses that often require hematologic consultation are emphasized. Systemic diseases that produce hematologic abnormalities that are similar in adults and children are discussed in other chapters (see Chapters 155 to 160). For a comprehensive review of the subject, readers are referred to a published textbook.[1]

INFECTIOUS DISEASE

Infection, especially viral infection, is the most common problem encountered by pediatricians. Although most infections do not produce significant hematologic sequelae, all classes of microorganisms have been implicated in the pathogenesis of hematologic abnormalities that range from mild and clinically irrelevant to severe and life threatening. This section describes the changes seen in red blood cells (RBCs), white blood cells (WBCs), platelets, and the coagulation system that are routinely encountered, are associated with a specific infection, or have a potentially serious clinical impact.

Changes in Red Blood Cells

The anemia of chronic inflammation or infection in children is similar to that seen in adults in terms of both clinical and hematologic findings and pathogenesis.[2] However, anemia with acute infections occurs more commonly in children than in adults.

Anemia of Acute Infections

A mild to moderate anemia of uncertain etiology may occur in the setting of both acute viral infections and more serious bacterial infections. In a study of children with mild viral or bacterial infections in the outpatient setting, anemia was documented in 5% of children 4 to 12 years of age, 17% of children 6 months to 4 years of age, and 33% of infants 6 to 11 months of age.[3] In 14 of 15 young children, the anemia resolved within 3 to 4 weeks. However, multiple mild infections may predispose infants to the development of a more chronic, mild anemia or low-normal hemoglobin that may be caused by iron deficiency, thus warranting a trial of iron supplementation.

Among children hospitalized with moderately severe inflammatory processes, the incidence of mild anemia (hemoglobin, 10.1-11.0 g/dL) is as high as 78%.[4] In a study of hospitalized children with either pyelonephritis bacteremia, average age 5 to 6 years, 60% had anemia.[5] No evidence of hemolysis was seen in this group of children. Follow-up hemoglobin in a subset of patients returned to normal without specific intervention. These data suggest that there is no indication to investigate the mild anemia of acute infection. Specific acute bacterial infections associated with a high incidence of anemia (44%-74%) include bone and joint infections, typhoid fever, brucellosis, and invasive *Haemophilus influenzae* infections.

The anemia associated with *H. influenzae* meningitis has been the most thoroughly studied of the anemias of acute infection. A majority of children with *H. influenzae* meningitis have mild anemia on admission, with hemoglobin in the 9 to 11 g/dL range, and up to 90% become anemic during the course of the illness.[6] This is in contrast with meningitis secondary to *Streptococcus pneumoniae* or *Neisseria meningitidis,* in which anemia is uncommon. The pathophysiology of the anemia of *H. influenzae* disease appears to be multifactorial. Shurin and associates[7] have shown that *H. influenzae* capsular polysaccharide, polyribosyl ribitol phosphate, binds to erythrocytes, which, in the presence of antibody and complement, can result in intravascular and extravascular hemolysis. They further hypothesize that polyribosyl ribitol phosphate alone may induce more rapid clearance of RBCs, perhaps on the basis of decreased RBC deformability. In addition, hypoferremia may limit bone marrow response to hemolysis.

Acute Hemolytic Anemia

Acute hemolysis has been observed with infections from all classes of microorganisms but is relatively uncommon. The anemia may be mild to severe, and the condition is manifested in children in either of two ways: (1) clinical presentation with symptoms and signs of infection predominating in a child subsequently found to have anemia or (2) clinical presentation with the manifestations of acute hemolytic anemia.

The mechanism of hemolysis in patients presenting with an infectious disorder depends on the infecting organism, but in most cases, hemolysis is extravascular.[8] Reported mechanisms include the following:

- Release of hemolysins (*Clostridium perfringens* sepsis)
- Invasion of the RBC (malaria)
- Alteration of the RBC surface:
 - Direct adherence by the organism (*Bartonella* spp.)
 - Alterations of antigenic phenotype by neuraminidase (influenza virus)
 - Cold agglutinins (*Mycoplasma* spp., *Listeria* spp., Epstein-Barr virus [EBV], *Leptospira* spp., *Rubella* spp.[8])
 - Absorption of capsular polysaccharide *(H. influenzae)*
- Mechanical mechanisms (microangiopathy associated with disseminated intravascular coagulation [DIC] or hemolytic uremic syndrome [HUS])
- Oxidative damage in persons with congenital enzyme deficiencies (e.g., hepatitis or brucellosis[9] with glucose-6-phosphate dehydrogenase [G6PD] deficiency, *Campylobacter jejuni* infection in neonates)

Acute, infection-associated hemolytic anemia in one study lagged behind the clinical infection by 3 to 7 days.[10] Most children were shown to have adsorption of microbial antigens to the RBC surface,

Table 154-1 Normal Hematologic Values in Childhood

									White Cells		Coagulation			
	Hb (g/dL)		RBCs Hct (%)		MCV (fl)		Total ($\times 10^3/\mu L$)		Neutrophils (%)	Lymphocytes (%)	PT (sec)*		aPTT (sec)*

aPTT, Activated partial thromboplastin time; *Hb,* hemoglobin; *Hct,* hematocrit; *MCV,* mean corpuscular volume; *PT,* prothrombin time; *RBC,* red blood cell.
*The normal range for the PT and APTT varies between laboratories. The time at which normal adult values are attained is 1 week for the PT and 2 to 9 months for the APTT. The platelet count is within the adult range from birth.

suggesting an "innocent bystander" mechanism of erythrocyte sensitization, ultimately leading to hemolysis. A minority of patients in this series had classic autoantibody-mediated hemolytic anemia.

Autoimmune hemolytic anemia (AIHA) in children usually is transient, is not associated with underlying systemic disease, and carries a low mortality rate. Children frequently have a history of concurrent or recently resolved infection, especially viral upper respiratory tract infection. Anti-cytomegalovirus (CMV) immunoglobulin G (IgG) has been implicated as the cause of acute AIHA in infants with CMV disease. Although mycoplasma pneumonia is usually associated with cold agglutinin syndrome, there is a report of multiple episodes of warm antibody-mediated hemolytic anemia in a child with Down syndrome.[11] Parvovirus has been rarely associated with AIHA. In some, but not all, cases, the Donath-Landsteiner antibody was identified.[12] In the typical acute, transient cases, 59% to 68% of children have a history of recent infection, but only 0% to 20% of those with the less common chronic course have such a history of infection.

Aplastic Crisis

Temporary arrest of RBC production has been observed in children with infections, but anemia is uncommon because of the long RBC lifespan. In two situations, however, severe anemia has been linked with infection and cessation of erythropoiesis: (1) B19 parvovirus infection in patients with an underlying hemolytic anemia and (2) transient erythroblastopenia of childhood.

The B19 parvovirus has been a known pathogen in animals for years but has only recently been linked with human disease.[13] It is the etiologic agent of fifth disease (erythema infectiosum), a mild illness with a characteristic "slapped cheek" facial erythema and a generalized reticular rash. In normal volunteers infected with B19 parvovirus, a mild, transient, and clinically irrelevant drop in the hemoglobin and reticulocyte count was observed.[14] In normal children, this infection usually is not associated with hematologic abnormalities, although reports of both hematologic and nonhematologic effects are increasing.[15] In children with sickle cell disease, spherocytosis, and other hemolytic anemias, B19 parvovirus infection can produce a severe anemia associated with peripheral reticulocytopenia and marrow erythroblastopenia—the "aplastic crisis." There may be other transient cytopenias noted during the RBC aplastic crisis.[16] Recovery within 1 to 2 weeks is the rule, but transfusion may be necessary.

B19 parvovirus infection also has been associated with prolonged anemia and reticulocytopenia in children with acute lymphoblastic leukemia (ALL) in remission, those with solid tumors receiving chemotherapy, those with immunodeficiency, those who have undergone renal transplantation, those with AIHA, and as the initial manifestation of human immunodeficiency virus (HIV) infection. Human parvovirus also has been identified as a cause of nonimmune hydrops fetalis.[17]

Transient erythroblastopenia of childhood (TEC) is a syndrome characterized by temporary arrest of RBC production with moderate to severe anemia in previously normal infants and toddlers. Although no specific infectious agent has been proved to cause TEC, the frequency of a history of infection within 1 to 3 months, the seasonal clustering, and the similarity to childhood idiopathic thrombocytopenic purpura (ITP) all suggest a possible viral etiology. B19 parvovirus has not been definitively associated with TEC.[18]

Changes in White Blood Cells

Children, as a rule, have the expected leukocyte response to infection. Infants and young children normally have a lymphocyte predominance (see Table 154-1), however, and any leukocyte response to infection must be judged on the basis of age-related normal values.

The predictive value of the peripheral WBC and differential counts in suspected bacterial infections has been extensively evaluated in infants and children. Todd has shown that in hospitalized children, a neutrophil count greater than 10,000/μL or band count greater than 500/μL is associated with an 80% chance of having a bacterial infection.[19] In children undergoing evaluation for possible meningitis, Lembo and colleagues[20] found that a ratio of immature to total neutrophils greater than 0.12 was more strongly associated with and more sensitive for bacterial meningitis than was the total WBC count or the total band count. Febrile children between the ages of 3 and 48 months are at increased risk for bacteremia, especially with *S. pneumoniae*. McCarthy and associates[21] demonstrated a threefold increase in risk of bacteremia in febrile (temperatures >40°C) children

younger than 2 years of age who had a WBC count of 15,000/μL or greater. In this setting, the WBC count was a more sensitive indicator of the presence of pneumonia or bacteremia than was the absolute neutrophil or band count. The degree of leukocytosis (i.e., >25,000/mm^2 vs. <15,000/mm^2) probably has no further discriminating ability.[22] Other studies have found both the WBC count and absolute neutrophil count (ANC) to be of value in differentiating bacterial from nonbacterial infection; the band count was not helpful.

There are recognized exceptions to the anticipated leukocyte response to infection that may serve as a clue to the diagnosis. In typhoid fever and brucellosis, leukopenia and neutropenia are prominent early in the illness. Shigellosis is associated with a variable leukocyte count, but the count often is normal, with a greater percentage of bands than neutrophils. Illnesses associated with lymphocytosis include pertussis (whooping cough), infectious lymphocytosis, infectious mononucleosis, and other viral infections. Neutropenia can be seen in bacterial sepsis from meningococci, pneumococci, staphylococci, and other bacteria and is associated with a poor prognosis. Black children (and adults) normally have lower WBC and neutrophil counts than those seen in whites; leukocyte and neutrophil response to serious infection may be decreased.[23]

Neutropenia

The most common cause of neutropenia (neutrophil count <1500/μL) in children is viral infection. A number of specific viruses are associated with neutropenia, including hepatitis virus, roseola virus, rubella virus, mumps virus, adenovirus, coxsackievirus A21, EBV, human herpesvirus-6 (HHV-6), and influenza virus.[24] The most common clinical setting, however, is the incidental discovery of neutropenia in a child with a nonspecific viral syndrome. Usually the neutropenia in this situation continues for less than 30 days and is rarely associated with infectious complications. In one large study of 1888 otherwise healthy children with fever and ANCs below 1000 cells/μL, there was only a 1.3% incidence of serious bacterial infection in children older than 3 months of age (one bacteremia, 13 urinary tract infections). The risk was higher in infants younger than 3 months of age (3.3%), similar to the risk of febrile infants of the same age without neutropenia.[25] Neutropenia also has been associated with a number of bacterial, rickettsial, and fungal infections.[26]

Eosinophilia

The most common cause of eosinophilia worldwide is parasitic infection. In the United States, visceral larva migrans *(Toxocara infestation)* is the most common cause of exaggerated eosinophilia (WBC count, 30,000-100,000/μL with 50%-90% mature eosinophils) in children.[27] Mild to moderate eosinophilia (≥600/μL) is most often seen in children with allergic rhinitis or asthma but also is characteristic of Chlamydia pneumonitis in infants.

Changes in Platelets or Coagulation

Thrombocytosis

Thrombocytosis (platelet count >500,000/μL) is known as an acute-phase reaction to infection, but it has been infrequently identified in children in the past. There is a particularly high incidence of reactive thrombocytosis in patients with bacterial infections, especially pneumonia with emphysema, and *H. influenzae* meningitis. Inflammatory cytokines, such as interleukin (IL)-1, IL-6, and thrombopoietin, may play an etiologic role in the reactive thrombocytosis of infection.[28] The vast majority of children with thrombocytosis have platelet counts between 500 and 700,000/μL, but 6% to 8% have counts between 700 and 900,000/μL and only 0.5% to 3% have platelet counts above 1,000,000/μL.[29] Thrombocytosis may be more common in simple acute infections than was previously recognized. Heath and Pearson[30] documented a 13% incidence of thrombocytosis in ambulatory patients; children with an increased platelet count were more likely to have a diagnosis of infection. In a Japanese study of more than 7500 hospitalized patients with platelet counts greater than 15,000, 6% of patients had thrombocytosis with an age-dependent incidence: 12.5% in neonates, 35.8% in 1-month-old babies, 12.9% in 6- to 12-month-old infants, then decreasing to 0.6% in 11- to 15-year-old children. Infection was the cause of the thrombocytosis in 67.5% of the cases.[31] Complications of reactive thrombocytosis are rare, but hemorrhagic or thrombotic complications may occur if there are additional acquired risk factors. Antiplatelet therapy is not indicated in patients with reactive thrombocytosis secondary to infection. Although the most common cause of thrombocytosis in children is infection, the list of considerations in the differential diagnosis of an elevated platelet count is extensive[32] and rarely includes underlying childhood malignancy.

Thrombocytopenia

Thrombocytopenia can be seen in patients who have infections with all types of organisms. Common viral agents include varicella virus, EBV, influenza virus, rubella virus, mumps virus, measles virus (wild or vaccine strains), HHV-6, hepatitis A virus, and CMV. The primary mechanism of the thrombocytopenia is immune destruction, although a direct viral effect on the platelet, megakaryocyte, or hematopoietic stem cell has been demonstrated. Because childhood ITP is thought to be secondary to infection in most instances, the definitions of "thrombocytopenia with infection" and "childhood ITP" tend to merge. Thrombocytopenia from infection usually is transient, although instances of chronic thrombocytopenia from specific viral infections (e.g., varicella or CMV) have been documented.[33,34]

Thrombocytopenia also is associated with bacterial sepsis. The low platelet count may be an isolated finding or associated with DIC. Corrigan[35] documented a 61% incidence of thrombocytopenia in 45 children with sepsis. The degree of thrombocytopenia was mild to moderate (64% had platelet counts >50,000/μL), but platelet counts ranged as low as 8000/μL. There was no evidence of DIC in 39% of those with low platelet counts. Thrombocytopenia in the setting of bacterial sepsis probably is also mediated by an immune mechanism with elevated platelet-associated IgG.

Petechial bleeding without thrombocytopenia can be seen in both bacterial and viral disease, especially that caused by meningococci, streptococci, and echoviruses. The explanation for the petechial rash in these infections is either vasculitis or platelet dysfunction.

Disseminated Intravascular Coagulation and Purpura Fulminans

Disseminated intravascular coagulation is uncommon after childhood infections and, if present, usually is accompanied by shock, with at least a 50% mortality rate. The most common organisms producing DIC are bacterial, especially the gram-negative bacteria (meningococci, *H. influenzae, Aerobacter* spp., and others) but also gram-positive organisms (*Staphylococcus aureus;* group B streptococci; *S. pneumoniae,* particularly in asplenic hosts; and *Bacillus anthracis*). DIC also is associated with disseminated viral (varicella, measles, rubella), rickettsial (Rocky Mountain spotted fever), fungal, mycoplasmal, and parasitic infections.

Purpura fulminans is a rare syndrome, seen in extremely ill children with DIC. Purpura fulminans is characterized by the rapid progression of ecchymotic skin lesions, especially of the extremities, that may progress to gangrene, ultimately resulting in amputation.[36] This syndrome has been described as a postinfectious purpura, with scarlet fever, upper respiratory tract infection, and varicella as the most common preceding illnesses and a latent period of 0 to 90 days after infection. A similar clinical picture can be seen in children with DIC and acute bacterial sepsis, especially meningococcemia.

Increasing evidence indicates that DIC with purpura fulminans is associated with deficiency of the naturally occurring anticoagulants. Children with postviral purpura fulminans have been shown to have acquired protein S deficiency, anti–protein S antibody, or the presence of a lupus anticoagulant.[37,38] In children with infectious purpura, protein C activation is impaired as reflected in low levels of protein C, protein S, and antithrombin. These findings are consistent with downregulation of the endothelial thrombomodulin–protein C receptor pathway.[39] The severity of protein C deficiency has been associated with increased morbidity and mortality.[40] There are minimal data on the frequency of inherited thrombophilia in children who develop purpura fulminans. In one report, the frequency of factor V Leiden was not different from that in healthy children; the presence of factor V Leiden was not associated with an increased mortality rate, although complications were increased.[41] In another study of 16 children with purpura fulminans, six of 16 (37%) patients studied had the actor V Leiden mutation. All of the children in this study survived, but 10 (63%) required amputation.[42]

Treatment of purpura fulminans consists of antibiotics for suspected bacterial infection, volume replacement for shock, and heparin. Although there is controversy regarding the routine use of heparin in DIC, its use in purpura fulminans has been associated with an improved outcome when it is started early in the course of the disease and continued for 2 to 3 weeks.[43] Theoretically, to improve the efficacy of heparin, it is reasonable to infuse fresh-frozen plasma or antithrombin III (AT III) concentrates[44] if the AT III level is low. There is anecdotal evidence that infusion of AT III concentrates or protein C concentrates partially correct or normalize the hemostatic abnormalities.[45,46] However, the KyberSept trial, a double-blind placebo-controlled trial of the use of ATIII concentrates in 2300 adults with sepsis, found no difference in mortality at day 28 after diagnosis.[47] In a phase II trial of protein C concentrate in the treatment of sepsis and purpura fulminans in children, there was dose-dependent activation of protein C and normalization of coagulation imbalances. Although there was no improvement in the mortality rate, the study was not powered to detect these changes.[48]

In initial trials recombinant human activated protein C (drotrecogin alfa activated) reduced the mortality rate in adults with severe sepsis,[49] but in pediatric trials, there was no noticeable improvement in mortality (children have a lower mortality rate than adults), and there were significant bleeding risks.[50,51] Although activated protein C has been used in patients with purpura fulminans, the data do not suggest a beneficial effect on mortality.[52,53] In October 2011, this agent was withdrawn from the market after a major study showed no efficacy for the treatment of sepsis. Recombinant tissue plasminogen activator (tPA) has been used in an attempt to restore organ perfusion by dissolution of diffuse microvascular thrombosis[54]; however, in a retrospective multicenter study of 62 patients with meningococcal purpura fulminans treated with systemic tPA, there was a high incidence of intracerebral hemorrhage without proven efficacy in reduction of mortality or incidence of amputation.[55] Other treatments, such as regional sympathetic blockade, topical nitroglycerin, and local infusion of tPA, have been used to improve regional blood flow to the affected part. The mortality rate for postinfectious purpura fulminans has declined from 90% in the past to 18%,[56] but the amputation rate has remained high.[42] The outcome for patients with acute bacterial sepsis and purpura fulminans has also improved, but a mortality rate as high as 50% continues to be reported.

Coagulation Inhibitors

Acquired inhibitors of coagulation in children with infection are usually transient and mild but may be associated with severe bleeding.[56] They are often detected after a viral illness, during antibiotic therapy, or incidentally (frequently before tonsillectomy or adenoidectomy). Both specific inhibitors of coagulation factors (especially factors VIII and IX) and lupus anticoagulants have been demonstrated. Although previously thought to be uncommon, studies have found 50% to 90% of children with infection have at least one positive test result for an antiphospholipid antibody (aPL).[57,58] Significant bleeding is usually seen only in children with specific factor inhibitors, although hemorrhage also has been described with lupus anticoagulants.[59] In symptomatic patients, treatment with prednisone has been associated with remission of bleeding manifestations. Complete resolution without recurrence is the most common event. Thrombosis in the setting of transient postinfectious coagulation inhibitors is rare, although splenic infarction from aPLs has been reported during infection with EBV and mycoplasma pneumonia.[60,61]

Pancytopenia

Pancytopenia in a child should alert the clinician to the possibility of disorders such as leukemia, aplastic anemia, or disseminated neuroblastoma. Infectious causes of pancytopenia are uncommon, and disseminated disease is most often present. Organisms implicated in patients with pancytopenia include *Mycobacterium tuberculosis,* atypical mycobacteria, *Histoplasma capsulatum, Leishmania* spp., *Salmonella typhi, Mucor* spp., Brucella spp., *Fusobacterium necrophorum, Mycoplasma pneumoniae,* and *Ehrlichia canis.*[26] Virus-associated or reactive hemophagocytic syndrome is an additional, although rare, cause of pancytopenia. Children with HIV infection and concomitant infection with *Mycobacterium avium-intracellulare* or parvovirus B19 have been reported to have pancytopenia.

Human Immunodeficiency Virus Infection in Children and Adolescents

Infection with HIV is more common in adults but is now recognized as a leading cause of immunodeficiency in infants and children.[62] Acquisition of HIV in a majority of infected children (most of whom are younger than 2 years of age) is by vertical transmission from an infected mother to her infant. Of children younger than 13 years with acquired immunodeficiency syndrome (AIDS), 80% have a parent with AIDS or AIDS-related complex (ARC), 13% have a history of blood transfusion, and 5% have hemophilia or another coagulation disorder.[63] With improvement in screening blood and blood donors for HIV, it is expected that vertical transmission from mother to infant will remain the primary method of transmission. Other "adult" routes of infection (homosexuality, intravenous needle use) are possible, especially in adolescents and sexually abused children.

Significant advances in the treatment of HIV infection in children have been made since the availability of antiretroviral therapy (ART). The transmission rate of HIV from an infected mother to her child has dropped to less than 2%. Rates of death, AIDS, opportunistic infection, and organ-specific disease (including thrombocytopenia) have all decreased since the advent of ART.[64] A review of HIV infection in children is available.[65]

The hematologic manifestations of AIDS in children are similar to those in adults (see Chapter 159) and depend on the stage of the HIV infection and the presence of coexistent disease.[66,67] Anemia is by far the most common finding (seen in 70%-90% of cases), although the incidence has decreased with effective antiviral therapy.[68] Moderate anemia (hemoglobin <8-9 g/dL) has been identified as an independent risk factor for disease progression in children.[69] Although there have been few studies of severe anemia (hematocrit <25%), in one study it correlated with development of an opportunistic infection and death within 7 months.[70] As in adults, inadequate RBC production is the most important pathogenetic mechanism for the anemia. The etiology for reduced erythropoiesis is multifocal, including direct effect of HIV, associated infections, medications, and deficiency of micronutrients.[69] Although Coombs-positive hemocytic anemia has been described,[71] studies suggest that the finding of a positive direct antiglobulin test result is more likely a reflection of

hypergammaglobulinemia. Although evidence indicates that erythropoietin may improve the hemoglobin and quality of life patients with HIV and anemia,[72] the evidence is not strong.[73]

Leukopenia and neutropenia are commonly seen in HIV-infected children (occurring in 47% and 41%, respectively), with severe neutropenia associated with opportunistic infections. Immune neutropenia and also circulating anticoagulants have been described. Lymphopenia is progressive but less prominent in children than in adults until late in the course.

Thrombocytopenia is present in 13% to 30% of pediatric AIDS patients and can be associated with clinically significant and even fatal hemorrhage. The mechanism of the thrombocytopenia in most cases is immune destruction, with a high percentage of patients having antiplatelet antibodies or immune complexes,[74] although amegakaryocytic thrombocytopenia has been reported.[60] Variable therapeutic responses to both corticosteroids and intravenous IgG have been demonstrated; some children have spontaneous remissions.[74,75] Thrombosis has also been described and is associated with severe disease.[76]

Isolated thrombocytopenia as a presenting manifestation of HIV infection has been reported in a number of children, usually infants and even in a neonate.[63,77] There have been no associated clinical stigmata of AIDS or ARC, and patients have been responsive to standard treatment (intravenous IgG or prednisone), often with sustained remissions. In a few patients with prolonged follow-up, no further manifestations of HIV infection were seen. Although it has been suggested that HIV testing may be indicated in all children with ITP, it seems most reasonable to check the HIV status of those with risk factors for AIDS and those outside the typical age group for ITP, especially infants.

COLLAGEN VASCULAR DISEASE AND ACUTE VASCULITIS

Juvenile Idiopathic Arthritis

Juvenile idiopathic arthritis (JIA) (formerly juvenile rheumatoid arthritis) includes a group of disorders with varied clinical presentation, course, and outcome. Systemic JIA, which occurs in 10% of patients, is a multisystem disease characterized by fever, rash, polyarticular (often destructive) arthritis, hepatosplenomegaly, and lymphadenopathy. New understanding of the pathogenesis of systemic JIA points to abnormalities in innate immunity (cytokines IL-1, IL-6, IL-18, neutrophils, and macrophages), distinguishing it from other forms of JIA, suggesting systemic JIA is an autoinflammatory syndrome rather than an autoimmune disease.[78] Another distinguishing feature of JIA is the association with macrophage activation syndrome (MAS) (see later discussion). Patients with JIA commonly demonstrate hematologic abnormalities that are proportional to disease activity. In the polyarticular presentation, more than four joints are involved, but the systemic findings are absent. This group, which accounts for 25% of patients, also may exhibit hematologic abnormalities. Pauciarticular JIA is characterized by involvement of fewer than four joints and is rarely associated with hematologic abnormalities.

Children with acute lymphoblastic leukemia may have a similar presentation as children with systemic JIA, which includes fever, joint pain, hepatosplenomegaly, and isolated cytopenias. Because about 5% of children with ALL are misdiagnosed as having JIA, it is important to perform bone marrow aspiration to rule out leukemia in any patient thought to have systemic JIA before initiation of corticosteroid therapy. Distinguishing features of children ultimately diagnosed with ALL after referral to a rheumatologist include atypical pattern of pain (nonarticular bone pain and night pain with no morning stiffness) and cytopenias, especially thrombocytopenia.[63]

The incidence of anemia is 50% to 60% in patients with systemic or polyarticular JIA and 10% in those with pauciarticular arthritis. The anemia usually correlates with disease activity, worsening during acute flare-ups; however, there is no relationship to the duration of illness. RBCs may be normochromic/normocytic or microcytic/hypochromic. The reticulocyte count usually is low. Iron studies often show low serum iron, increased free erythrocyte protoporphyrin, low-normal or elevated total iron-binding capacity, and normal or low serum ferritin. Serum erythropoietin levels usually are mildly elevated (but not as high as in iron deficiency). The bone marrow does not show erythroid hyperplasia in response to the anemia and has diminished (but not absent) iron stores. The etiology of the anemia may be chronic disease, iron deficiency, or both.

Although it is difficult to differentiate anemia of chronic disease from iron-deficiency anemia, studies in patients with systemic-onset chronic JIA suggest defective iron supply as the primary cause.[79] Transferrin receptor levels are inversely related to hemoglobin levels in this population. The finding of elevated serum transferrin receptor levels may be a reliable indicator for diagnosis of iron deficiency in JIA.[80] Oral iron has been effective in raising the hemoglobin in iron-deficient anemic patients with JIA, and intravenous iron has been effective in raising the hemoglobin level in children unresponsive to oral iron.[79] Excessive production of IL-6, tumor necrosis factor-α (TNF-α), and other inflammatory cytokines has been documented in patients with JIA and may provide an explanation for the abnormalities in iron metabolism. IL-6 may enhance ferritin synthesis and increase hepatic uptake of serum iron. Increased ferritin results in reticuloendothelial iron blockage and diminished iron absorption.[79] In one study, treatment with anti–TNF-α therapy, the hemoglobin as well as markers of abnormal iron metabolism, improved significantly.[81] Less common causes of anemia in patients with JIA include erythroid aplasia, suppression of erythropoiesis by circulating inhibitors, hemolysis, and a macrocytic anemia probably related to increased folate clearance and low plasma and RBC folate levels.

In systemic JIA, leukocytosis with mean WBC counts up to 30,000/μL and neutrophilia with a left shift occur in 90% of patients, especially those with active disease. Leukocytosis is less common in polyarticular arthritis and usually absent in pauciarticular disease. Leukocytosis is so prevalent in systemic JIA that the presence of neutropenia should alert the clinician to question the diagnosis and ensure that other possibilities such as systemic lupus erythematosus (SLE) and ALL are not overlooked. Nonetheless, neutropenia has been reported in several patients with JIA.[82] Other causes of neutropenia are bone marrow suppression due to therapy with gold or nonsteroidal antiinflammatory drugs (NSAIDs)[83] and, in adults, Felty syndrome, the triad of rheumatoid arthritis, splenomegaly, and neutropenia.

The platelet count is elevated in about half of the patients with systemic JIA. IL-6, a cytokine that stimulates thrombopoiesis, is elevated in patients with active systemic JIA, and increased levels of IL-6 are correlated with elevated platelet counts.[84] Persistent thrombocytosis may serve as an adverse prognostic marker for long-term outcome in JIA.

Thrombocytopenia may result from bone marrow suppression by gold therapy, the rare consumptive coagulopathy, or platelet trapping in Felty syndrome. Thrombocytopenia is also seen in the potentially life-threatening complication of MAS (see MAS below). Because thrombocytopenia is uncommon in JIA, however, an unexplained low platelet count should lead the clinician to consider alternative diagnoses, such as SLE or ALL. On the other hand, isolated thrombocytopenia may be the only presenting sign in a child who later develops JIA or another collagen vascular disease. Therefore, JIA and SLE should be considered in the differential diagnosis of ITP in children who are older than 9 years of age and female. Appropriate screening tests for autoantibodies (e.g., antinuclear antibody assay, direct Coombs test) should be performed at diagnosis and periodically if new symptoms develop.

Disseminated intravascular coagulation may occur in children with systemic JIA after hepatic damage, as part of the MAS, from aspirin or gold therapy, or during disease flare-ups treated with NSAIDs when serum albumin is low.[85] These patients often are very

ill and may require early and aggressive medical therapy as well as platelet and coagulation factor replacement to control the coagulopathy. The incidence of coagulation abnormalities in nonbleeding patients with systemic JIA is controversial. One study demonstrated prolonged prothrombin time (PT) and activated partial thromboplastin time (aPTT) and elevated fibrinogen, factor VIII, and fibrinopeptide A levels in up to 50% of these patients,[86] but other reports have not confirmed such findings. Another study found elevation of D-dimer levels in 96% of systemic-onset JIA patients; serial measurements of D-dimer levels appeared to parallel response to treatment.[87] In apparent distinction, decreased fibrinolytic activity and increased plasminogen activator inhibitor have been found in patients with active JIA, especially those with the systemic form. Antibodies against factor VIII and the lupus anticoagulant are occasionally seen in children with JIA.

Macrophage Activation Syndrome

Macrophage activation syndrome is a life-threatening multisystem disorder most closely resembling hemophagocytic lymphohistiocytosis (HLH) that occurs primarily in patients with systemiconset juvenile idiopathic arthritis (sJIA). This syndrome usually occurs early in the course of active sJIA and can even be a presenting feature,[88] although it has been reported to occur later and during a quiescent phase.[89] It is estimated that approximately 7% of patients with sJIA develop MAS, and the mortality rate is between 10% and 20%.[90] MAS has also been reported in other systemic inflammatory disorders, including SLE and Kawasaki disease.[88]

The main clinical features of MAS include a high unremitting fever, hepatosplenomegaly, lymphadenopathy, bleeding, rash, and central nervous system manifestations. Neurologic symptoms include lethargy, irritability, disorientation, headache, seizures, and coma. Children with MAS are acutely ill, and almost 50% require intensive care unit care.[91] The diagnosis may be delayed because the presentation mimics an acute exacerbation of sJIA or severe infection. Of interest, some patients have shown a paradoxical improvement in the underlying inflammatory disease at the onset of MAS. Precipitating factors that have been implicated include a flare-up of the underlying disease, aspirin or other NSAID toxicity, viral infections, a second injection of gold salts, methotrexate, and sulfasalazine therapy.[91]

Typical laboratory features include pancytopenia, hypofibrinogenemia (<250 mg/dL), elevated liver enzymes (>40 IU/mL), hypertriglyceridemia (>160 mg/dL), and marked elevation of ferritin (>10,000 ng/mL). Other laboratory findings with less sensitivity and specificity include coagulopathy, hyponatremia, and hypoalbuminemia. The hallmark of this disorder is the presence of hemophagocytic histiocytes usually seen in the bone marrow, although they can also be found in the liver and other organs. These characteristic macrophages are regarded as confirmatory evidence rather than a requirement for a diagnosis because they have not been documented in as many as 20% of patients with the classical clinical and laboratory findings of MAS.[91,92]

There are no accepted diagnostic criteria for MAS in sJIA. Preliminary diagnostic guidelines have been proposed (Table 154-2), although they have not been validated in prospective studies.[92] An international consensus survey of diagnostic criteria for MAS was completed by 232 physicians.[93] The top nine diagnostic criteria identified by more 50% of respondents in order of frequency were:

1. Falling platelet count
2. Hyperferritinemia
3. Bone marrow hemophagocytosis
4. Increased live enzymes
5. Falling leukocyte count
6. Persistent continuous fever >38°C
7. Falling erythrocyte sedimentation rate
8. Hypofibrinogenemia
9. Hypertriglyceridemia

Table 154-2 Preliminary Diagnostic Guidelines for Macrophage Activation Syndrome in Systemic Juvenile Idiopathic Arthritis*

Laboratory Criteria

1. Decreased platelet count (≤262 × 10^9/L)
2. Elevated levels of aspartate aminotransferase (>59 IU/L)
3. Decreased white blood cell count (≤4.0 × 10^9/L)
4. Hypofibrinogenemia (≤250 mg/dL)

Clinical Criteria

1. Central nervous system dysfunction (irritability, disorientation, lethargy, headache, seizures, coma)
2. Hemorrhages (purpura, easy bruising, mucosal bleeding)
3. Hepatomegaly (≥3 cm below the costal margin)

Histopathologic Criterion

Evidence of macrophage hemophagocytosis in the bone marrow aspirate

Diagnostic Rule

The diagnosis of MAS requires the presence of any two or more laboratory criteria or of ≥2 clinical or laboratory criteria. A bone marrow aspirate for the demonstration of hemophagocytosis may be required only in doubtful cases.

From Ravelli A, Magni-Manzoni S, Pistorio A, et al: Preliminary diagnostic guidelines for macrophage activation syndrome complicating systemic juvenile idiopathic arthritis. *J Pediatr* 146:598, 2005.
MAS, Macrophage activation syndrome.
*The suggested criteria are useful only in patients with active systemic-onset juvenile idiopathic arthritis. The laboratory thresholds are examples only and are not specific for the diagnosis (see text).

These features may give us the best candidates for future refinement of diagnostic criteria. The diagnostic guidelines are similar to criteria for the diagnosis of HLH,[94] although a number of differences should be emphasized. In MAS, clinical features are weaker discriminators than laboratory features. Although the presence of fever was universal in patients with MAS, it had a low specificity rate because of the high incidence of fever in patients with sJIA without MAS. The pattern of fever may be of more importance because patients with MAS tend to have nonremitting fever as opposed to the high spiking fevers seen in sJIA. The other clinical criteria may occur late in the course of MAS, resulting in abnormal laboratory findings being more helpful in making a diagnosis early in the course of the illness. Because blood counts are usually elevated in patients with sJIA, the decrease in counts seen with MAS may actually result in a "normal" blood count, although in patients with HLH, cytopenias are usually well below the normal levels. Laboratory markers of T-cell activation (soluble IL-2 receptor [SCD25]) and of macrophage activation (soluble CD163 [SCD163]) have been shown to be elevated in patients with MAS and may serve as useful diagnostic markers in the future.[95]

The pathogenesis of MAS is similar to that proposed for HLH.[94,96] Indeed, it has been proposed that MAS be considered one of the subtypes of acquired HLH.[90] The presentation of MAS is a result of an ineffective immune response to an endogenous or exogenous stimulus leading to an exaggerated inflammatory state produced by a release of high levels of cytokines. These proinflammatory cytokines include TNF-α, IL-1, IL-6, IL-8, IL-12, IL-18, macrophage inflammatory protein (MIP 1-a), and interferon-γ (INF-γ) released by stimulated lymphocytes and histiocytes. Defective natural killer (NK) cell function and cytotoxic T-cell activity has been documented in patients with MAS as well as HLH and may be the common pathway leading to the clinical presentation.[97] NK function in patients with active sJIA but without MAS has also been found to be abnormal.[98] This may explain why MAS is almost exclusively seen in the systemic form of JIA and not the other subtypes of the disease. Mutations in the perforin gene and the *MUNC 13-4* gene have been described in some patients with HLH. The cytotoxic function of NK cells is mediated by the release of perforin and other cytolytic granules into the

target cell, leading to cell death. Abnormalities of both perforin gene and *MUNC 13-4* polymorphisms have been found in patients with MAS.[97,99,100]

Treatment of MAS should be started promptly and not delayed for lack of hemophagocytosis if the clinical and laboratory features are consistent with the diagnosis. The initial treatment should be high-dose corticosteroid therapy followed by cyclosporine A if there is not a rapid response. Intravenous methylprednisolone with doses from 2 to 30 mg/kg/day has been the most common corticosteroid reported in the literature and is usually effective in controlling hyperinflammation.[91] The corticosteroid of choice used in the treatment of HLH is dexamethasone, but its use has not been reported in MAS. Cyclosporine A has been very effective in inducing remissions either when used as initial treatment or in cases of corticosteroid failure.[89,91] In addition to immunosuppression, there should be withdrawal of any suspected triggering medications and treatment of infection. Intravenous immunoglobulin (IVIG) therapy has usually been ineffective, although it has been reported to induce a full recovery in one case of a child who failed high-dose corticosteroids.[101] For unresponsive patients treatment with etoposide or other HLH salvage therapy may be necessary. Etanercept and infliximab have also been reported to induce clinical responses in patients with MAS.[102-104] These drugs are recombinant soluble TNF-α receptor fusion proteins that bind to TNF-α, blocking its effect. Although use of these agents to reduce the elevated levels of TNF-α found in this disorder is attractive, they should be used with caution because there are case reports of MAS developing after the initiation of etanercept.[105] Anakinra, a recombinant IL-1 receptor antagonist, has shown promising results in treatment of systemic JIA as well as MAS.[105,106]

Kawasaki Syndrome

Kawasaki syndrome is an acute multisystem disorder characterized by an abrupt onset of fever unresponsive to antibiotics; bilateral conjunctival injection; reddening of the lips, tongue, or oral mucosa; reddening, induration, or peeling of the skin on the hands or feet; polymorphous truncal rash; and cervical lymphadenopathy. This disorder occurs most commonly in children younger than 2 years and has many features of a severe vasculitis. The most serious complication is development of coronary artery aneurysms, which occurs in 20% of children and is responsible for the 3% mortality rate; death often is caused by coronary artery thrombosis or rupture. The etiology of Kawasaki disease is unknown. The immunologic and clinical characteristics of this disorder are similar to those of diseases associated with superantigen production, of which toxic shock syndrome is a classic example.[107]

Children with Kawasaki syndrome may have a mild normochromic, normocytic anemia with reticulocytopenia. Rare patients with AIHA have been reported. Leukocytosis is almost universal, with mean neutrophil counts of 21,000/μL. Ninety-five percent of patients have neutrophilia, with a left shift persisting up to 3 weeks. The finding of vacuoles and toxic granulation in neutrophils is a helpful adjunct in the diagnosis of Kawasaki disease. Activated neutrophils and monocytes may play a role in aneurysm development through the production of elastase. Granulocyte colony-stimulating factor levels have been correlated with coronary artery dilatation during the acute phase of Kawasaki syndrome.[108]

Studies of cellular immunity show normal total T-cell numbers but decreased suppressor T cells, causing relatively elevated T helper–cell levels during the first 4 weeks of disease.[109] The change of T-cell subsets plus B-lymphocyte stimulation may contribute to the exaggerated production of all major immunoglobulin classes during the first 8 weeks of the disease.[110] An unusual infiltration of IgA-producing plasma cells within vascular tissue in Kawasaki syndrome, with an oligoclonal IgA response, suggests that the immune stimulation is antigen driven.[111] Circulating immune complexes and high C3 (but not C4) levels are found during weeks 1 and 3. During the acute phase, increased levels of the cytokines IL-1, IL-6, IL-8, INF-γ, and TNF are noted in the circulation, and IL-1, IL-2, INF-γ, and TNF in blood vessels and skin biopsies.[107] Declining serum IL-6 levels appear to correlate with clinical response after treatment with IVIG.[112]

Impressive thrombocytosis occurs in 85% of patients by the second week, peaking during the third. Platelet counts of up to 2 million/μL are not uncommon, and the mean platelet count is 700,000/μL. Thrombocytosis may serve as a marker of possible atypical Kawasaki disease in infants younger than 1 year of age. In a study of more than 25,000 infants with unexplained fever, 8.8% with a platelet count greater than 800,000/μL were found to have Kawasaki disease as opposed to 0.4% of those with a platelet count less than 800,000/μL.[113] Thrombocytosis is preceded by elevated thrombopoietin levels.[114] However, 2% of patients may have thrombocytopenia caused by a consumptive coagulopathy. Platelets demonstrate hyperaggregation on exposure to adenosine diphosphate, epinephrine, and collagen in vitro. These abnormalities may persist for as long as 9 months after diagnosis.[115] During the first month, levels of factor VIII, fibrinogen, thromboxane B_2, and thromboglobulin are increased. AT III and fibrinolysis activity are decreased. The PT, aPTT, and thrombin time usually are normal.[116]

Prevention and treatment of existing coronary aneurysms constitute the primary therapeutic goal. Aspirin suppresses platelet aggregation but does not affect aneurysm formation. Combining aspirin with high-dose IVIG infusions reduces aneurysm formation, decreases fever, and normalizes laboratory signs of inflammation.[117] The use of corticosteroids is controversial, with conflicting data regarding increased aneurysm formation after steroid usage.[118-120] However, in a randomized, double-blind, placebo-controlled trial, a single pulsed dose of intravenous methylprednisolone, in addition to conventional therapy, did not improve coronary artery outcomes.[121,122] In subgroup analysis of children with persistent fever, coronary outcomes were better in the corticosteroid group. If children at highest risk of primary treatment failure could be identified initially, corticosteroid use may be of benefit in this group. Infliximab has been used in the treatment of IVIG-resistant patients with limited success.[123] Guidelines for the diagnosis, treatment, and long-term management of patients with Kawasaki syndrome have been published.[121,124]

Henoch-Schönlein Purpura

Henoch-Schönlein purpura (HSP) (anaphylactoid purpura) is a systemic vasculitis characterized by unique purpuric skin lesions, transient arthralgias or arthritis (especially affecting the knees and ankles), colicky abdominal pain, and nephritis. Recognition of HSP is important, not so much for its hematologic abnormalities (which are rare) as for the unusual nonthrombocytopenic purpuric lesions, which are frequently confused with the hemorrhagic rash of ITP. This vasculitis occurs most commonly in children 3 to 7 years old, often 1 to 3 weeks after an upper respiratory tract illness. The presenting sign in 50% of children is a characteristic rash, which may begin as urticaria. As these eruptions fade, they are replaced by brownish-red maculopapular lesions and petechiae. The petechiae coalesce, forming areas of raised or "palpable" purpura on the buttocks, legs, and extensor surfaces of the arms, with a symmetrical distribution. The rash may fade but can recur for months, especially with increased activity. Children younger than 3 years of age often have painful soft tissue swellings of the scalp and face (especially periorbital areas) and on the dorsa of the hands and feet. Infantile acute hemorrhagic edema is an acute vasculitis affecting infants younger than 2 years, which may be a benign form of HSP.

Sixty-seven percent of patients experience colicky abdominal pain, often associated with vomiting, hematemesis, or melena from submucosal hemorrhage and edema of the small bowel wall. With severe edema, the bowel wall may become a leading point for intussusceptions.[125]

Renal involvement occurs in 50% of patients, especially boys and older children, and may present after initial systemic symptoms. Hematuria, either microscopic or gross, may occur with proteinuria during the first 3 weeks of the illness but rarely after 6 months. With

progressive involvement, hypertension, impaired renal function, and renal failure can occur in up to 15% of children, with an associated mortality rate of 3%. In occasional patients, an acute scrotum that mimics testicular torsion may develop; however, surgical exploration may not be necessary if appropriate clinical and radiographic features are present. Other rare manifestations of HSP include neurologic, cardiac, and pulmonary events.

Anemia occasionally develops as a result of gastrointestinal (GI) tract blood loss or decreased RBC production caused by renal failure. The leukocyte count is normal. Despite the impressive purpura, the platelet count is normal or increased with normal platelet function. Coagulation factor levels usually are normal, although transient decreases in factor XIII activity and vitamin K deficiency from severe vasculitis-induced intestinal malabsorption have been reported. Signs of increased fibrinolysis, as evidenced by elevation of D-dimer and other markers, have been described.[126] Bleeding in the GI tract; the lungs; or, rarely, the central nervous system is caused by a necrotizing vasculitis and not a hemostatic defect.[125] Hypercoagulability does not play a role with normal frequency of MTHFR, prothrombin, and factor V Leiden gene mutations.[127]

Henoch-Schönlein purpura is considered an IgA-mediated inflammation of small vessels. Biopsy of skin or other involved tissue reveals a leukocytoclastic vasculitis. Immune complexes of IgA with complement, IgG, or IgM have been found circulating in the serum[128] and deposited in blood vessel walls of the kidneys and in intestinal and skin lesions.[129] The mechanism of production, accumulation, and deposition of IgA immune complexes in the blood vessel is unclear. It has been suggested that HSP may be a systemic form of IgA nephropathy.[130] Both disorders have identical features on renal biopsy and are characterized by mesangial proliferation, occasional focal sclerosis, and crescent formation.[131]

Treatment is mainly supportive, although corticosteroids have been found to provide symptomatic relief with severe joint, scrotal, or abdominal pain.[132,133] They do not alter skin involvement or prevent renal involvement. Recent studies have suggested that corticosteroids plus azathioprine, cyclosporin A, or cyclophosphamide may have a role in the management of severe renal involvement.[134-138] Rituximab has been reported to be effective in decreasing the symptoms of three patients with severe, refractory chronic HSP.[139] The prognosis is good for full recovery except in children with renal failure.

CARDIOPULMONARY DISEASE

Congenital Heart Disease

Congenital heart disease (CHD) occurs in about 1% of live births. Structural heart malformation usually follows predictable patterns such that six defects account for 70% of all cardiac disorders: ventricular septal defect, atrial septal defect, tetralogy of Fallot, patent ductus arteriosus, pulmonary stenosis, and aortic stenosis. Children with cardiac abnormalities may be acyanotic or cyanotic, depending on the underlying lesion. Hematologic abnormalities occur most often in children with cyanotic CCHD. Polycythemia is the bone marrow response to chronic hypoxemia in patients with CCHD. The decreased arterial oxygen content stimulates erythropoietin production, which in turn increases erythropoiesis. The resultant increased RBC mass increases the oxygen-carrying capacity of the blood, resulting in improved tissue oxygenation. With adequate compensation, erythropoietin levels fall to normal, and higher RBC production is maintained. A second compensatory mechanism is an increase in 2,3-diphosphoglycerate (2,3-DPG) levels in the RBC when the arterial oxygen tension is less than 70 mm Hg. The higher 2,3-DPG level causes a right shift of the oxyhemoglobin curve, resulting in greater oxygen release to the tissues.

Polycythemia in cyanotic children is beneficial up to a point. Because the relationship between the hematocrit and blood viscosity is hyperbolic, minor increases in the hematocrit above 70% cause marked increases in blood viscosity. This higher viscosity results in impaired perfusion within the microvasculature with ultimately less tissue oxygen delivery. The impairment is magnified in severe polycythemia (hematocrit level >75%) such that headache; irritability; dyspnea; and even formation of pulmonary, renal, or central nervous system thrombi may result.[140] To prevent these complications, the hematocrit level should be maintained around 60% through the use of exchange transfusions. Small aliquots of the patient's blood are slowly removed and replaced by equal volumes of plasma or 5% albumin. Care should be taken to remove blood slowly because vascular collapse, cyanosis, stroke, and seizures have been reported with too rapid an exchange. Apheresis (erythrocytapheresis) also has been shown to be an effective means of decreasing viscosity in polycythemic patients.

Infants with CCHD are at risk of developing iron-deficiency anemia. The deficiency may result from the combination of poor iron stores at birth (especially in premature infants), increased iron needed for enhanced erythropoiesis, poor iron intake because of poor feeding, and ongoing iron losses as a consequence of phlebotomy or exchange transfusion. These children may exhibit symptoms of iron deficiency (irritability, anorexia, poor weight gain) or worsening cyanosis. The hemoglobin may be normal for age but inappropriately low for the degree of hypoxemia. Low RBC indices and hypochromic, microcytic RBCs are the best indices of iron deficiency in this setting.[141] Polycythemic children with iron-deficiency anemia are at increased risk for cerebral vein thrombosis because of the poor deformability of the iron-deficient RBC, which further increases blood viscosity.[142] To prevent this complication and to allow for maximal tissue oxygenation, all infants should be fed iron-rich infant formula and receive iron replacement therapy as needed to normalize RBC indices.

Hemolytic anemia, characterized by mechanical destruction of RBCs and manifested by the presence of schistocytes in the peripheral blood smear, is occasionally seen after the placement of prosthetic heart valves.

Routine screening of patients with CHD has demonstrated coagulation abnormalities in 20% to 59% of children with acyanotic defects and in 40% to 50% of those with cyanotic heart disease (Table 154-3).[143] Only 11% of children with CCHD have any clinical evidence of bleeding preoperatively. However, children with underlying hemostatic defects have a greater frequency and severity of postoperative bleeding.[143,144] Presurgical screening tests should include at least a platelet count, platelet function assay (e.g., closure time), PT, and aPTT. Further investigations may be indicated if there is a history of bleeding or abnormal results on screening tests. Acquired von Willebrand syndrome has been reported in patients with CHD and is possibly associated with an increased bleeding risk, especially in those receiving aspirin. The multimer pattern reveals decreased large-molecular-weight multimers.[145] Children with polycythemia have contracted plasma volumes; therefore, when blood samples are collected, extra care should be taken to ensure the proper 1:9 ratio of 3.8% sodium citrate to blood to prevent artificial abnormalities in coagulation test results.

The etiology of the coagulation abnormalities in CCHD is unclear. Earlier reports suggesting a role for consumptive coagulopathy have not been confirmed. Protein C levels in eight of 29 term infants with CCHD were significantly lower than in control participants with no evidence of familial deficiency. Of these infants, two had thrombotic complications, and four had consumptive coagulopathy.[146] Platelets have shortened survival times (even with normal counts), and normal to increased numbers of megakaryocytes in the bone marrow are reported.[147] This increased platelet destruction does not appear to be attributable to DIC. Both the platelet and coagulation abnormalities are directly proportional to the degree of hypoxemia and polycythemia. For example, whereas children with oxygen saturations greater than 60% have a mean platelet count of 315,000/μL, those with saturations less than 60% have a mean count of 185,000/μL.[147] The mild platelet and coagulation abnormalities usually are decreased or corrected after surgical repair of the heart defect.[143,148] With bleeding or if surgery is not possible, the coagulopathy may be treated by correction of polycythemia to a hematocrit level of 60% by using slow plasma-exchange transfusion.[149]

Table 154-3 Coagulation Abnormalities in Congenital Heart Disease

Abnormality	Incidence (%)	
	Acyanotic CHD	Cyanotic CHD
Prolonged bleeding time	11	28
Prolonged PT		20
Prolonged aPTT		19
Thrombocytopenia	12-40	0-36
Abnormal platelet aggregation	14	38-70
Increased fibrinolysis	12	0-10
Abnormal clot retraction	10	
Low fibrinogen	16	12
Increased fibrin split products		Occasionally
Decreased factors II, V, VII, VIII, IX, X, XI, XII		Occasionally
Decreased protein C		25*

Cystic Fibrosis

Cystic fibrosis (CF) is a multisystem disorder of exocrine gland dysfunction characterized by chronic pulmonary disease, pancreatic exocrine insufficiency, hepatic dysfunction, abnormal reproductive organ function, and intestinal obstruction associated with abnormally high sweat electrolyte levels. It is an autosomal recessive disease with an incidence of one in 2000 live births.

Severe hemolytic anemia caused by vitamin E deficiency may be the presenting manifestation of CF. Dolan[150] initially linked deficiency of vitamin E with severe hemolytic anemia in infants who presented with pallor, edema, hypoproteinemia, and thrombocytosis. This complication can be seen as early as 6 weeks of age.

Many children with CF are chronically hypoxic, yet they do not have the expected augmented erythroid response. In a study by Vichinsky and colleagues,[151] none of 42 children with CF had polycythemia, and 30% (especially the boys and the older children) had a normochromic, normocytic or hypochromic microcytic anemia with reticulocytopenia. In contrast with children with CCHD, there was no appropriate increase in RBC 2,3-DPG levels, no right shift of the oxyhemoglobin curve, and either a low or a normal erythropoietin level. In vitro assays showed normal erythroid progenitor cell numbers and no serum inhibitor of erythropoiesis. Up to 66% of the children studied had abnormalities consistent with iron deficiency, and all responded to oral or parenteral iron therapy.

It appears that the etiology of anemia in CF is multifactorial. A blunted erythropoietic response to hypoxia plus iron deficiency secondary to iron malabsorption or poor dietary iron intake may each be partially responsible for the development of anemia. If iron deficiency persists despite adequate oral supplementation, the possibility of ongoing blood loss or of iron malabsorption that may necessitate parenteral iron replacement should be considered. Soluble transferrin receptor levels may be helpful in distinguishing iron deficiency from anemia of chronic inflammation in CF because, unlike serum ferritin and transferrin, soluble transferrin receptor does not appear to be an acute phase reactant.[152,153]

Use of multiple antibiotics in patients with CF is routine. There have been a number of case reports of adult patients with severe, life-threatening hemolytic anemia attributed to piperacillin.[154,155] This complication has not been reported in children at this time.

Findings of studies of neutrophil function in children with CF are conflicting. Some reports indicate impaired chemotaxis, chemiluminescence, granule release, and superoxide production,[156-158] but others have demonstrated factors in patient sputum that actually enhance neutrophil and monocyte responses to stimulants.[159,160] Although these sputum factors may improve neutrophil killing ability, they also may worsen neutrophil-mediated lung damage through increased release of neutrophil elastase.[161] Evaluation of immune function has revealed impaired lymphoproliferative responses to *Pseudomonas* spp. and other gram-negative bacterial antigens, defective opsonization, increased levels of circulating immune complexes, and decreased numbers of T-helper cells in 30% of patients.[138,162] The contribution of these findings to frequent pulmonary infection is still under investigation.

Children with CF usually do not experience clinically significant bleeding owing to impaired hemostasis despite the risk of liver disease and vitamin K deficiency from malabsorption. An exception may be infants younger than 1 year of age, in whom rare case reports of vitamin K–deficient hemorrhage have been reported in association with CF.[163-165] Routine coagulation tests usually yield normal results, with an occasional prolonged PT reported. A study by Corrigan and colleagues[142,166] revealed that 60% of 24 patients had a more subtle deficiency of prothrombin activity, thought to be caused by vitamin K deficiency. Other investigators, using direct measurement of vitamin K and PIVKA-II (protein induced by vitamin K absence-II), have reported conflicting percentages of patients to be vitamin K deficient,[167,168] with another uncontrolled study demonstrating normalization of PIVKA-II values in many patients by routine administration of daily oral vitamin K.[169] Routine vitamin K supplementation is recommended for all patients with CF,[170] although there are inadequate data to define the ideal dose.[171]

Children with CF appear to have a particularly high predisposition to recurrent venous thrombosis. In one study of 19 patients with recurrent venous thrombosis, six had CF, but none of 101 thrombosis patients without recurrence had CF. A striking association with respiratory tract colonization with *Burkholderia cepacia* was noted, as was the frequent presence of a central venous catheter. Several of the recurrences occurred while on therapeutic anticoagulation.[172] Studies of small populations of both children and adults had documented an increased incidence of protein C and protein S deficiency, as well as lupus anticoagulants.[173-175] These abnormalities are likely acquired defects in most CF patients because of the potential for having subclinical vitamin K deficiency, liver function abnormalities, and recurrent infections. Follow-up studies have not shown persistent abnormalities in many patients. The incidence of activated protein C resistance and factor V Leiden was similar to the general population. Although it would be anticipated there would be an increased frequency of venous thrombosis because of the increased use of central venous catheters, at least one large study in older adolescents and adults with CF who had totally implanted venous access devices revealed a very low incidence of complications.[176] Whether patients with CF have a greater risk of venous thrombosis than the control population awaits a larger prospective controlled trial.

HEMATOLOGIC MANIFESTATIONS OF CHILDHOOD GASTROINTESTINAL DISEASE

Milk Protein–Induced Enteropathy and Heiner Syndrome

The association of iron deficiency with dietary intake of cow's milk in young infants is established. A major contributing factor is the relatively poor bioavailability of iron in cow's milk compared with breast milk. In addition, the rapid growth of infants and

corresponding rapid increase in RBC mass necessitate an increased requirement for dietary iron. The role of cow's milk in inducing occult GI blood loss in infants was carefully documented more than 3 decades ago in a sentinel paper that also demonstrated a correlation between the amount of milk ingested and the amount of fecal blood lost.[177] GI blood loss in response to cow's milk ingestion appears to be most prevalent in infants younger than 6 months of age and occurs with diminishing frequency in older infants.[178] The majority of affected infants outgrow their milk protein sensitivity by 3 years of age. The GI blood loss may be ameliorated by heat denaturing of the milk proteins. Occasionally, toddlers and older children have been documented to have milk-induced GI bleeding with associated iron-deficiency anemia.[179,180] Substantially limiting cow's milk consumption and prescribing iron supplementation is sufficient to correct the iron deficiency and associated hypoproteinemia with edema in most children.[181]

A variety of GI syndromes associated with cow's milk sensitivity, with varying manifestations and severity, has been described. Associated findings may include vomiting, diarrhea, poor growth, and hypoproteinemia; however, some patients may have occult blood loss and iron-deficiency anemia without associated complaints. At the severe end of the spectrum, cow's milk protein–induced enterocolitis may occur.[182] Such patients may present with acute, severe bloody diarrhea; vomiting; abdominal distention; methemoglobinemia; and shock even in the absence of anemia.[182] Even minute amounts of cow's milk protein in human breast milk may be sufficient to precipitate a severe event.[183] In patients with chronic occult GI blood loss, esophagogastroduodenoscopy may reveal gastritis or gastroduodenitis, and colonoscopy may demonstrate modest histologic abnormalities in the proximal colon.[177,180] The immunopathobiology of cow's milk protein allergy syndromes has not been fully elucidated. Most of these syndromes affecting the intestinal tract only are non–IgE mediated.[177] Wilson et al[177] reported the frequent presence of precipitating antibodies to milk proteins in the study population as a whole. However, the presence of such antibodies did not appear to predict milk-induced GI bleeding. The roles that genetic predisposition, intestinal and immunologic immaturity in young infants, exposure to cow's milk protein in breast milk, GI infections, or other factors may play in the development of milk protein enteropathy are not fully understood.

In 1962, Heiner et al described a syndrome in infants and young children that included chronic cough, recurrent lung infiltrates, poor growth, GI symptoms and blood loss, iron-deficiency anemia, and pulmonary hemosiderosis associated with multiple serum precipitins to cow's milk proteins. Others have confirmed and further detailed this rare syndrome. Additional manifestations may include intermittent wheezing; hilar lymphadenopathy; eosinophilia; elevated levels of serum IgE, IgM, or IgA; chronic rhinitis; adenoidal hypertrophy; hypercapnia; and cor pulmonale. A feature of this syndrome is rapid improvement of the pulmonary manifestations after eliminating cow's milk from the diet.

Celiac Disease

Celiac disease, or gluten sensitive enteropathy, is an inflammatory and malabsorptive process resulting from an aberrant intestinal T-cell immune response to ingested dietary gluten, leading to injury of the mucosa of the small intestine.[177] Classical celiac disease has been characterized as frequently affecting infants and young children, leading to steatorrhea, failure to thrive, weight loss, and nutritional deficiency. With the advent of improved screening techniques, the prevalence is recognized to be greater than previous estimates. Celiac disease broadly affects both children and adults, many of whom may have minimal classical symptoms of the disorder. Treatment is usually institution of a gluten-free diet, with resolution of the process in the majority of cases.

Iron deficiency is frequently present in celiac disease in children and adults and may be the sole recognized manifestation of the disorder.[165] Dietary iron absorption primarily occurs within the proximal small intestine, the same region most affected by celiac disease. As a result, iron deficiency in celiac disease appears to be primarily caused by impaired absorption of dietary iron, although a component of chronic GI blood loss may also apply in a minority of patients. Iron deficiency in celiac disease may be refractory to iron supplementation, and a significant percentage of children and adults with iron-deficiency anemia that does not respond to therapeutic oral iron replacement have celiac disease.

Folic acid and, to a lesser frequency, vitamin B_{12} deficiency may also result from the malabsorptive process in celiac disease. Manifestations may include macrocytic anemia, leukocytopenia, and pancytopenia. Neurologic findings may be present with vitamin B_{12} deficiency. Other vitamin and micronutrient deficiencies, including copper and vitamin K deficiency, have been observed in celiac disease. Splenic hypofunction may occur with some frequency in adults with celiac disease but appears to be less common in children. A number of case reports have suggested an association of pulmonary hemosiderosis with celiac disease. The pathophysiology of this association is not known, but the pulmonary process may improve with initiation of a gluten-free diet.

A high index of suspicion is important for diagnosing celiac disease in children, particularly those who are minimally symptomatic or who may be at increased risk for development of celiac disease. The latter group includes children with trisomy,[21] Turner syndrome, IgA deficiency, autoimmune thyroiditis, and type 1 diabetes, and those with a family history of celiac disease. In addition to correcting the nutritional deficiencies and growth failure in children with celiac disease, recognition of the disease and institution of a gluten-free diet may minimize the risk of some of the associated conditions of celiac disease, including the development of non-Hodgkin lymphoma involving the intestinal tract.

Inflammatory Bowel Disease

Anemia is a very common extraintestinal manifestation of inflammatory bowel disease (IBD), particularly in children with Crohn disease, in whom the historical prevalence of anemia approaches 70% to 80%. A more recent series of studies suggests that the prevalence of anemia may be declining in Crohn disease, perhaps because of more effective therapy.[178] The etiology of anemia in IBD appears to be multifactorial, but the most common contributing factors are iron deficiency related to chronic GI blood loss or iron malabsorption caused by intestinal mucosal injury and decreased absorption and sequestration of iron stores as is seen in the anemia of chronic inflammation. These broad mechanisms for anemia may coexist, and it is sometimes difficult to determine the predominant mechanism. Measurement of serum soluble transferrin receptor and the hemoglobin content of reticulocytes can be helpful in this setting.[178] Other contributing factors to anemia in IBD may also be present in individual patients, including immune-mediated hemolytic anemia, hemophagocytosis, malnutrition, folate and vitamin B_{12} deficiency, and the suppressive effects of medications on hematopoiesis.[178]

Specific treatment of anemia in IBD may be difficult. Oral iron supplementation is not always effective. Comparative studies of oral versus intravenous iron supplementation suggest the intravenous route may result in better short-term improvement in anemia; however, long-term outcome data are lacking.[178] Some patients may respond to supplemental erythropoietin administration as well.[178] Patients with IBD may have impaired enterocyte-mediated intestinal absorption of iron, the degree of which appears to correlate with disease activity.[184] The role that induction of hepcidin expression by mediators of inflammation, particularly IL-6, plays in the anemia of IBD is an intriguing area of ongoing investigation.

Other hematologic manifestations of IBD include leukocytosis and thrombocytosis, hyposplenism, an increased propensity toward thrombosis, and therapy-related leucopenia and thrombocytopenia. There may be an increased incidence of immune-mediated thrombocytopenia associated with IBD. The recently described potential association between infliximab, an anti-TNF antibody, and

hepatosplenic T-cell lymphoma bears close observation and suggests that biologic agents such as infliximab should be used only after careful consideration of the potential benefits and risks of the agent in the individual patient.

Other Gastrointestinal Disorders

In addition to the disorders already discussed, other GI disorders that occur in children and adolescents may be associated with the development of anemia. Examples include antral gastritis, duodenal and colonic polyps, parasitic infestations, and GI malignancies. GI stromal tumors, although rare, usually present in teenage girls with anemia related to GI blood loss.[185] In a recent small experience of endoscopic evaluation of the upper GI system in children and teenagers between the ages of 9 and 17 years presenting with iron-deficiency anemia who did not have hematologic or chronic diseases, heavy menstrual flow or obvious blood loss demonstrated abnormal finding in 57% of patients.[186] This small study suggests that careful evaluation of the GI system should be considered in children and adolescents with unexplained iron-deficiency anemia and in those in whom the iron deficiency does not correct appropriately with oral iron supplementation.

ENDOCRINE DISEASE

Hematologic Manifestations of Thyroid Disorders

The associations between thyroid disorders and hematologic abnormalities are diverse.[177] The most commonly reported findings include anemia of several etiologies and abnormalities of hemostasis. Specific associations in childhood and adolescence appear to be less common than in adults. However, some rare disorders with both hematologic and thyroid manifestations appear to be particularly pertinent to the pediatric population.

Congenital hypothyroidism has multiple etiologies, including thyroid agenesis, thyroid-stimulating hormone resistance, disorders in thyroid hormone production, and central hypothyroidism. Screening programs for congenital hypothyroidism have been widely adopted as part of neonatal screening programs for several decades, resulting in marked improvement in the clinical manifestations of congenital hypothyroidism. A series of 50 infants with congenital hypothyroidism identified by neonatal screening found that modest normocytic, normochromic anemia, correlating with the severity of the hypothyroidism, is present during the first year of life despite thyroid hormone replacement.[178] By comparison, a separate publication of infants also identified by neonatal screening demonstrated no anemia, and six of 23 infants were found to be polycythemic.[179] The differences in these reports is not understood but may reflect, in part, the differences in the pathophysiology of congenital hypothyroidism.

The association between autoimmune thyroid disease and anemia is well recognized. The anemia may be exacerbated by several mechanisms, including iron deficiency, pernicious anemia, and AIHA. In adults, the anemia of uncomplicated hypothyroidism is typically normocytic or macrocytic, with modest anisocytosis present on the peripheral smear.[177] In children and adolescents, the same findings appear to be present. Additionally, children may have a decrease in linear growth velocity as a manifestation of hypothyroidism, suggesting that investigation of thyroid function is appropriate for children with macrocytic anemia and declining growth rate.[180] Pernicious anemia and iron deficiency may be less common in children with autoimmune thyroid disease than in adults. However, parietal cell antibodies are found in a significant percentage of children and adolescents with autoimmune thyroid disease, a finding that may predispose them to the development of both iron-deficiency and pernicious anemia during young adulthood.[181]

Disturbances of hemostasis are also well recognized as a manifestation of thyroid dysfunction. Overt hypothyroidism and hyperthyroidism modify the hemostatic balance in opposite directions, with hypothyroid patients having an increased risk of bleeding and hyperthyroid patients having an increased risk of thrombosis.[182] There are few reports of bleeding or thrombosis in children and adolescents attributed to uncomplicated overt thyroid dysfunction. Of interest is the association between acquired von Willebrand disease and hypothyroidism reported in several adolescent girls, which may be a cause of menorrhagia.[183,187,188] This hemostatic imbalance may improve with thyroid hormone replacement.

More global immune dysregulation syndrome may result in both endocrine dysfunction, including thyroid abnormalities, and cytopenias. The association of the autoimmune polyglandular syndrome, a heterogenous group of disorders, and pernicious anemia has been reported in children.[189] Additionally the immunodysregulation, polyendocrinopathy, and enteropathy, X-linked (IPEX) syndrome, which is caused by loss-of-function mutations of the *FOXP3* gene, has been associated with immune cytopenias, including hemolytic anemia, neutropenia, and thrombocytopenia.[190]

ANOREXIA NERVOSA

Anorexia nervosa is a psychiatric disorder occurring in about one in 800 adolescent girls; it is characterized by an inability to maintain a minimal normal body weight, intense fear of being fat, body image distortion, and amenorrhea. The profound weight loss is accompanied by hypothermia, hypotension, edema, lanugo, and metabolic changes and is associated with a mortality rate of 5% to 18%. A mild, normochromic, normocytic anemia with reticulocytopenia occurs in 30% of patients.[191] Acanthocytes or spur cells have been reported and may be caused by low serum α-lipoprotein levels. The causes of the anemia probably are decreased RBC production and a relative increase in plasma volume. A few patients have had slightly decreased RBC survival. Serum vitamin B_{12} and folate levels usually are normal. Despite low serum iron and decreased bone marrow iron stores in 80% of patients, iron-deficiency anemia is uncommon except during recovery, when iron supplementation is necessary. The severe hypophosphatemia seen during refeeding of severely malnourished patients has been associated with hemolytic anemia.

Fifty percent of patients have leukopenia, with an absolute decrease in numbers of neutrophils, lymphocytes, and monocytes.[192,193] The neutropenia may be quite severe. An increased incidence of infection is not usual, although with increasing use of central venous catheters, more serious bacterial infections are being reported.[193] Bone marrow reserves are normal despite marrow hypoplasia and a normal to slightly decreased size of the marginal pool. Impaired neutrophil chemotaxis, intracellular killing of staphylococci, and decreased complement levels have been demonstrated in patients with anorexia. These findings are associated with occasional skin abscess formation.

Patients with anorexia nervosa have no apparent bleeding diathesis. The platelet count is normal to slightly decreased,[191,194] and the in vitro platelet aggregation response to epinephrine, adenosine diphosphate, and collagen is exaggerated. Coagulation defects are uncommon except for that related to vitamin K deficiency reported in bulimia.

The hematologic changes in anorexia nervosa are directly correlated with total body fat mass depletion.[195] A bone marrow pattern on magnetic resonance imaging suggestive of gelatinous transformation of bone marrow (serous atrophy) is seen in patients with the lowest hematologic parameters. Direct examination of the bone marrow reveals hypoplasia with loss of fat stores and replacement by a gelatinous acid mucopolysaccharide ground substance. Focal or extensive necrosis may be present.[196] Bone marrow histiocytes are relatively increased in number and have prominent blue-green granules. With nutritional supplementation, bone marrow hypoplasia reverses, the gelatinous material disappears, and the hematologic abnormalities, including neutrophil defects and low complement levels, resolve by 8 weeks.

THROMBOEMBOLIC COMPLICATIONS IN CHILDHOOD ILLNESS

Improvements in medical and surgical care, particularly advances in critical and supportive care, have led to increased survival among children with malignancy and chronic illnesses. However, the extended survival of these children has led to comorbidities such as thromboembolic complications. The increased risk of thromboembolism in children with chronic illnesses is multifactorial and can include the illness itself, medical and surgical interventions, or the central venous line used to administer therapy.

In a recent analysis of 13,449 admissions at United States children's hospitals, the majority (63%) of patients with venous thromboembolism had one or more complex chronic conditions, most commonly cardiovascular disease (28%), followed by malignancy (14%), neuromuscular (11%), and respiratory (7%).[172] This review focuses on four childhood illnesses commonly associated with thromboembolism: malignancy, CHD, nephrotic syndrome, and SLE. In addition to the diseases discussed in this review, other chronic illnesses of childhood have been associated with thromboembolism, including sickle cell anemia, IBD, diabetes, and CF. Children receiving home total parental nutrition also have an increased risk of thrombosis due to the combination of a central venous catheter and infusion of hyperosmolar solutions that can injure the vascular endothelium.[197,198] As the incidence of pediatric venous thromboembolism increases, the concept of thromboprophylaxis in hospitalized children is receiving increased attention. The end of this section will review the small but growing body of literature on this topic.

Thromboembolism in Pediatric Cancer

Although thrombosis is a well-known complication of pediatric malignancy, the overall incidence is low compared with adults with cancer. Most epidemiologic studies in this area have been limited to single-center experience or specific cancer types. The reported incidence of thromboembolism in pediatric cancer ranges from 2% to 14% when based on clinical symptoms and up to 44-50% when children undergo routine radiographic screening.[199-206] In a report of 17 years' experience at McMaster's Children's Hospital, 7.9% (95% confidence interval, 6.0%-10.0%) of oncology patients experienced thromboembolism. Increasing age, certain cancer types (hematologic malignancies and sarcomas), intrathoracic disease, and catheter dysfunction were associated with a higher risk of thromboembolism.[206] Because many thrombotic events in pediatric cancer are catheter related, the majority of thrombosis described in the literature is located in the upper venous system. Factors associated with an increased risk of catheter-related thrombosis include insertion of peripherally inserted central catheters or Hickman catheters and a history of catheter occlusion and infection.[207] Right atrial thrombi are also frequently seen, with a reported incidence of 9% to 14% in children with indwelling catheters.[203,208] Typically asymptomatic, these thrombi are often found incidentally on routine surveillance echocardiograms for children receiving anthracycline chemotherapy. Patients with asymptomatic catheter-related thrombosis are at risk for postthrombotic syndrome (persistent pain, swelling, or skin changes) after catheter removal, and screening cancer survivors for these symptoms should be part of the long-term follow-up care for these patients.[207]

There are several mechanisms by which malignancy increases the risk of thromboembolism.[209] These include direct activation of the coagulation system; inhibition of fibrinolysis through secretion of plasminogen activator inhibitor-1; and the release of cytokines, which themselves induce procoagulant and antifibrinolytic activity. Malignant cells can also adhere to platelets, leukocytes, and the endothelium through adhesion molecules present on their surfaces. Finally, as tumors increase in size, they may compress or occlude blood vessels, leading to reduced blood flow and stasis.

Published studies indicate that patients with hematologic malignancies and sarcomas appear to have the highest risk of thromboembolism. In a meta-analysis including 1752 children with ALL, the incidence rate for thrombosis was 5.2%.[210] As opposed to other types of cancer, cerebral venous thrombosis and stroke are frequently seen in ALL, particularly in the setting of asparaginase therapy. Asparaginase, an essential component of induction chemotherapy, reduces the synthesis of both coagulation factors and inhibitors as a consequence of asparagine depletion.[211] Higher incidences of thrombosis appear to be associated with lower doses of asparaginase given over longer treatment durations, as well as prednisone (when given instead of dexamathasone).[210]

The incidence of thromboembolism in sarcoma ranges from 14% to 16%.[212,213] Thrombotic events in sarcoma are frequently detected at the time of presentation and may be asymptomatic. Patients with greater disease burden or metastatic disease appear to be at highest risk. Brain tumors, the most common solid tumor in children, have a relatively lower risk of thrombosis in children compared with adults. Pediatric and adolescent studies have reported incidences of 0.5%, 0.6%, and 2.8% as opposed to the 18% to 28% incidence of thrombosis in adults with brain tumors.[206,214-216] Because the incidence of thromboembolism increases with age, this complication is of particular concern in adolescents and young adults with cancer, an increasing number of whom are cared for at children's hospitals. In a study of 2001 to 2008 national discharge data from U.S children's hospitals, 5.3% of adolescents and young adults (15-24 years of age) with cancer had a discharge diagnosis of venous thromboembolism.[217] Large prospective cohort studies including pediatric patients with all types of malignancies are needed to better understand the true incidence of thromboembolism in pediatric cancer.

Thromboembolism in Congenital Heart Disease

Although CHD affects only 1% of live births, almost 50% of infants younger than 6 months of age and 30% of older children who develop venous thromboembolism have underlying cardiac disorders.[218] Also, the majority of children receiving prophylactic anticoagulation are those with complex CHD or severe acquired cardiac diseases such as cardiomyopathy. Children with CHD are at risk of venous, arterial, and intracardiac thrombosis, as well as embolism to the central nervous system. CHD is the most common associated diagnosis among children hospitalized with arterial ischemic stroke in the United States.[219]

Cardiac catheterization is the most common procedure performed in children with CHD, and it is used for both diagnostic and therapeutic purposes. Access is typically obtained through the femoral artery. Historically, thromboembolism of the femoral artery was a common complication of this procedure, particularly in younger patients. In the 1970s, a randomized clinical trial demonstrated that the use of unfractionated heparin prophylaxis reduced the incidence of femoral artery thrombosis from 40% to 8% in children younger than 10 years of age.[220] The current recommendation from the American College of Chest Physicians (ACCP) is that all children should receive prophylaxis with unfractionated heparin before cardiac catheterization, using a bolus of 100 to 150 U/kg, with additional doses recommended for prolonged catheterizations.[221,222]

The Fontan procedure, which diverts systemic venous return directly to the pulmonary arteries, is the definitive palliative surgical treatment for most congenital univentricular heart lesions.[223] Unfortunately, thromboembolic events continue to be a major cause of morbidity and mortality in this procedure. The reported incidence of these complications in cohort studies ranges from 1% to 19% and includes venous thrombosis of the Fontan circuit, right atrial thrombosis, and stroke.[223] Thromboembolic events may occur anytime after the procedure but often present months to years later.[224] There is no consensus as to the optimal type or duration of anticoagulation that Fontan patients should receive, nor are there data that any one prophylactic regimen is effective in reducing thromboembolic complications. Institutional protocols, if they exist, range from no anticoagulation to aspirin to warfarin. The ACCP guidelines suggest either therapy with aspirin (1-5 mg/kg/day) or therapeutic heparin

followed by warfarin to achieve a target international normalized ratio (INR) of 2.5 but state that the optimal duration of therapy is unknown.[221,222] In a recently published international randomized trial of aspirin (5 mg/kg/day) versus warfarin as primary thromboprophylaxis in the first 2 years after Fontan surgery, there was no difference in thrombosis rates between groups.[225] However, the overall thrombosis rate was suboptimal, suggesting that alternative approaches need to be considered.

There are even less data on the role of anticoagulation or antiplatelet therapy in other cardiac procedures with the potential risk of thromboembolism. These include the placement of endovascular stents and Blalock-Taussig shunts as well as Norwood and Glenn procedures, which are typically performed before the definitive Fontan procedure. The ACCP recommends perioperative heparin therapy for these procedures.[221,222] However, the need for antiplatelet therapy after these procedures remains unknown.

Recombinant activated factor VII (rVIIa) is increasingly used as a hemostatic adjunct in pediatric cardiac surgery. In two of three single-center studies, thrombotic complications were not increased in patients receiving rFVIIa compared with those who did not receive rFVIIa during surgery.[226-228] However, prospective adequately powered studies are required to properly assess the safety of this prothrombotic agent in patients with CHD.

Long-term anticoagulation therapy is clearly indicated for children with prosthetic heart valves. This population is currently treated according to adult recommendations.[229] Children with mitral bioprosthetic valves should receive three months of warfarin followed by long-term aspirin therapy, but those with aortic bioprosthetic valves can be managed with aspirin alone. Those with mechanical valves must remain on long-term warfarin, with target INRs of 2.5 or 3.0 depending on the specific type of valve. Patients with mechanical valves and a history of thromboembolism or additional thrombotic risk factors should also receive low-dose aspirin.

Thromboembolism in Nephrotic Syndrome

The increased risk of thromboembolism in pediatric nephrotic syndrome is multifactorial.[230] The same urinary losses that lead to profound hypoalbuminemia in these patients also cause acquired deficiencies of anticoagulant proteins such as antithrombin and free protein S. In addition to deficiencies of anticoagulants, increased levels of procoagulants (fibrinogen, factor V, and factor VIII), hypercholesterolemia, and increased platelet aggregation have all been described in nephrotic syndrome. Finally, the therapeutic interventions for nephrotic syndrome can increase the risk of thromboembolism. Diuretics cause reduced intravascular volume, leading to hemoconcentration, and steroids and cyclosporine increase procoagulant activities.

The incidence of thromboembolism in pediatric nephrotic syndrome ranges from 1.8% to 9.2% in published series.[230-233] This contrasts with adult nephrotic syndrome, in which incidence rates as high as 44% have been reported.[231] The most common locations in children are the deep veins of the lower extremities and renal veins, and events are frequently associated with the use of central venous catheters. Although pulmonary embolism is clinically diagnosed in fewer than 1% of patients, a frequency of 27% (seven of 26) was found in a series of nephrotic children who underwent screening with ventilation–perfusion scans.[234] These data suggest that pulmonary symptoms may not always be caused by fluid overload in this population and that pulmonary embolism should at least be considered in any nephrotic patient with a significant change in respiratory status.

Prophylactic anticoagulation is recommended for adult nephrotic syndrome as long as the patient has proteinuria or severe hypoalbuminemia. However, no studies have been performed to evaluate the efficacy or safety of this practice in pediatric patients, and prophylaxis is generally not used in children without a history of thrombosis.[235] One reason for the controversy is that predictors of thrombosis have not been clearly established in this population. Even decreased plasma concentrations of antithrombin, a well-recognized risk factor, is not a consistent finding in nephrotic children who develop thromboembolism.[236] The most consistent biologic risk factor to date is the presence of severe hypoalbuminemia.[230] Age 12 years or older at diagnosis of nephrotic syndrome, severe proteinuria, and history of thromboembolism preceding the diagnosis of nephrotic syndrome have also been identified as significant predictors of thromboembolism.[233]

Although the traditional duration of anticoagulation for a deep venous thrombosis (DVT) is 3 months, some form of anticoagulation should be continued or resumed in the setting of active disease.[222] To avoid hemoconcentration, diuretics must be avoided or used judiciously in patients who have experienced a thromboembolic event. Finally, it is important to remember that the efficacy of heparin can be impaired in the setting of decreased antithrombin levels.

Thromboembolism in Systemic Lupus Erythematosus and Antiphospholipid Syndrome

The reported incidence of thromboembolism in pediatric SLE ranges from 9% to 17%, similar to rates reported in adult SLE patients.[237,238] Although DVT of the lower extremities is still the most common manifestation, patients with SLE are more likely to experience arterial and central nervous system thrombosis compared with those with malignancy, CHD, or nephrotic syndrome. In approximately half of cases, thrombosis occurs before or at the time of SLE diagnosis.[239] The significant association between the presence of aPLs and thromboembolism is well described in patients with SLE.[240] aPLs are a heterogenous group of antibodies directed against plasma proteins and phospholipid complexes. They most frequently occur in the setting of SLE but are also associated with JIA, epilepsy, and other diseases.[241] There are multiple aPLs subtypes, including lupus anticoagulants, anticardiolipin antibodies, anti-β_2-glycoprotein I antibodies, and antiprothrombin antibodies. The exact mechanism of aPL-associated thromboembolism has not been elucidated, but recent data suggest that lupus anticoagulant antibodies interfere with the function of the protein C pathway, leading to an acquired activated protein C resistance.[242]

Antiphospholipid antibodies are quite common in the pediatric SLE population. An analysis of 12 published series of children with SLE reported a global prevalence of 48% for anticardiolipin antibodies and 23% for lupus anticoagulants.[241] Recent work has focused on the predictive value of aPL subtypes for the risk of thromboembolic events. In a cohort of 58 children with SLE, the presence of lupus anticoagulants had the highest predictive power for thromboembolism.[243] The presence of anticardiolipin antibodies was also predictive but only if they were persistent (positive on at least two occasions 3 months apart). Other studies have confirmed the strong predictive power of aPLs, particularly lupus anticoagulants, for the risk of thromboembolism.[237,244,245] However, pediatric SLE patients who are negative for aPLs rarely develop thrombotic events.

Based on these data, it is recommended that children with SLE be routinely screened for lupus anticoagulants, and if antibodies are present on more than one occasion, families should be counseled on the presenting symptoms of stroke and other thrombotic events.[245] Prophylaxis with low-dose aspirin may be reasonable, especially in the setting of other thrombotic risk factors. However, there are not yet data to support routine prophylactic anticoagulation in SLE patients with lupus anticoagulants in the absence of a history of thromboembolism.[237] Patients who develop DVT can be treated with the standard 3 months of anticoagulation. However, all children with systemic inflammatory disorders such as SLE, rheumatoid arthritis, and IBD are at risk for recurrent thrombus when their inflammatory process is exacerbated. Therefore, children with systemic inflammation and a history of thrombosis should receive prophylactic anticoagulation until the inflammation is well controlled.[221,246]

It is important to note that transient lupus anticoagulants, likely the result of infections or immunizations, have been well described in healthy children. These incidentally found antibodies are not associated with an increased risk of thrombosis or bleeding. There are also patients with antiphospholipid syndrome (APS), defined as a

thrombotic event and persistence of aPL positivity for at least 12 weeks after diagnosis, who do not have underlying SLE, although they may develop the disease later.

The management of thromboembolism in primary and secondary APS is different from most other pediatric thromboembolisms. Patients with APS have a high risk of thrombus recurrence off therapy, and most affected children are treated indefinitely.[239,246] However, the appropriate duration or intensity of prolonged therapy is not known. The international Ped-APS registry was established in 2004, and a published report of the first 121 patients has provided insight into the clinical and immunologic manifestations of pediatric APS.[239] As opposed to adults, pediatric APS is only slightly more frequent in girls (female:male ratio, 1.2:1), likely because women with recurrent fetal losses are not included in this population. Similar to adults, approximately half of patients present with primary APS. Thrombotic events are diverse and include DVT of the lower extremities (40%), arterial ischemic stroke (26%), and cerebral sinus vein thrombosis (7%). Multiple aPL positivity is frequent (81% with anticardiolipin antibodies, 72% with lupus anticoagulants, and 67% with anti–β_2-glycoprotein I antibodies), but two-thirds of patients tested negative for one or more of the aPL tests, emphasizing the importance of testing for all subtypes in clinical practice. Nineteen percent of pediatric patients with APS experienced a recurrent thrombotic event, even higher than the numbers reported in adult patients.[247,248]

Thromboprophylaxis During Childhood Illness

The use of thromboprophylaxis to prevent hospital-acquired venous thromboembolism has become the standard of care in adult institutions. Even though the risk of thrombosis in hospitalized children is much lower than in adults, there are patients in pediatric hospitals (particularly adolescents and young adults) who deserve systematic screening for thrombosis risk and application of prophylactic measures.[249] Multicenter prospective studies are required to determine the safety and efficacy of prophylaxis, as well as the age cutoff at which prophylaxis should begin to be considered, yet these studies will be very difficult to complete because of the relative rarity of thrombosis in the pediatric setting. In a single-center prospective safety evaluation of anticoagulation prophylaxis in high-risk patients 14 years of age and older, there have been no major bleeding complications.[249]

The 2008 ACCP guidelines discuss the use of thromboprophylaxis in only a few specified settings.[222] The guidelines recommend prophylaxis for children receiving long-term home parenteral nutrition and for patients with complex cardiac conditions and associated procedures. Routine prophylaxis is not recommended in children with central venous lines (including those with cancer).

Most studies of thromboprophylaxis in children with chronic disease have been in the setting of ALL. Because central venous catheters are the most important risk factor in the development of cancer-related thrombosis, investigators have sought to determine if thromboprophylaxis is effective in preventing this complication. Studies have shown that thromboprophylaxis is well tolerated in children with cancer.[205,250,251] However, a randomized trial demonstrated no difference in the incidence of line-related thrombosis between pediatric cancer patients receiving low-dose warfarin (goal INR, 1.3-1.9) and those in the control group.[252] A predictive model incorporating high-dose prednisone, asparaginase in combination with steroids, the presence of a central venous catheter, and the presence of inherited thrombophilias has demonstrated validity in the ability to identify children at high risk of thrombosis in a large population of children with ALL.[253] As a secondary outcome of this study, high-risk patients without low-molecular-weight (LMWH) prophylaxis showed significantly reduced thrombosis-free survival during induction therapy compared with those who did receive prophylaxis (LMWH was administered according to preference of the treating physician) (see box How to Manage Thromboembolism in the Setting of Pediatric Cancer).

How to Manage Thromboembolism in the Setting of Pediatric Cancer

When treating thromboembolism in a patient with cancer, LMWH is the preferred choice. Warfarin, although it is less expensive and can be given orally, is difficult to regulate in the setting of multiple chemotherapy agents, frequent invasive procedures, and changing vitamin K stores because of antibiotics and illness.[205,254,255] A randomized clinical trial in adult cancer patients demonstrated that LMWH was more efficacious and as safe as warfarin in preventing recurrent thromboembolism.[256] The 2008 ACCP guidelines recommend the use of LMWH in the treatment of cancer-related venous thromboembolism for a minimum of 3 months and until the precipitating factor (e.g., use of asparaginase) has resolved.[222] Other practical suggestions have been reported, but none are supported by any systematic observations.[213,222,254]

- A minimum of two doses of LMWH should be held before lumbar punctures and other invasive procedures.
- For intramuscular asparaginase injections, applying firm pressure and administering the medication at the trough of the anti-Xa level are probably adequate to avoid bleeding.
- Clinicians should maintain platelet counts above 50,000/μL in the first 2 weeks of anticoagulation. After that time period, the LMWH dose should be adjusted according to platelet count (50% dosing for platelet counts 20-50,000/μL; hold doses for platelet counts <20,000/μL).

Asparaginase-Related Thrombosis

Management of asparaginase-related thrombosis in ALL can be particularly challenging, and the Dana-Farber Cancer Institute has recently published its experience rechallenging pediatric and adult patients with asparaginase after a first thrombosis.[257] In this retrospective review, survival was similar in patients with and without thrombosis, and the following guidelines were suggested:

- Asparaginase can be resumed when symptoms of thrombosis have resolved and there is evidence of clot stabilization or improvement on repeat imaging, typically after about 4 weeks of anticoagulation.
- Because of the protein depletion experienced by patients receiving asparaginase, anti-Xa levels should be monitored frequently.
- If LMWH at previously adequate doses no longer adequately anticoagulates the patient, antithrombin levels should be checked and antithrombin repleted as necessary.

HEMATOLOGIC COMPLICATIONS OF SOLID ORGAN TRANSPLANTATION IN CHILDREN

The frequency and the success of solid organ transplantation in children have been increasing over the past decade. In 2004, there were 1816 transplants in children representing 7% of all recipients.[258,259] This is an increase of 13% over the previous decade. Of the transplants in 2004, the majority were renal transplants (765) followed by liver (529) and then heart (250-290). The success rate has been also improving impressively, with 5-year survival after kidney transplant at 95% to 96%, liver transplant 79% to 83%, and cardiac transplant 70% to 75%.

Hematologic complications after solid organ transplantation are a common problem. Although most of the evidence regarding the type, frequency, and etiology of these complications has been studied in adults,[260] there are increasing reports in children. After renal

transplantation, 60% of children are reported to be anemic. After liver transplant, 36% of children will have a hematologic problem, and of these, 54% are anemic events, 19% anemia and neutropenia, 12% thrombocytopenia, 8% neutropenia, and 2% pancytopenia.[261] After heart, heart–lung, or double lung transplant, 51% of patients have been reported to have hematologic problems, including 49% anemia, 14% neutropenia, 14% thrombocytopenia, and 23% anemia plus neutropenia with or without thrombocytopenia.[262] The etiology of these hematologic problems is most commonly a result of infection followed by medication effect. Miscellaneous causes include blood loss, microangiopathic hemolytic anemia, autoimmune cytopenias, posttransplant lymphoproliferative disease (PTLD), and multifactorial.

In the next section, discussion of the hematologic complications of solid organ transplantation is divided into cell type and by organ type when feasible. The incidence, etiology, and natural history of the problem are addressed. Much of the data are derived from adult studies, but information from pediatric studies is emphasized.

Red Blood Cells

Anemia is a common problem after transplantation, occurring in 66% of kidney transplant recipients at the time of transplant[263] and 60% to 84% after transplant.[264] In liver transplant recipients, the incidence is 20% to 35%,[261,265,266] and in recipients of heart or heart–lung or double lung, it is 30% to 70%.[262,267] There are distinct patterns of presentation of the problems associated with RBCs, including early posttransplant anemia, HUS/microangiopathic hemolytic anemia (MAHA), late anemia from immunosuppressant drugs (ISDs), late anemia from other causes, and pure RBC aplasia (PRBCA).

Early Posttransplant Anemia

Early posttransplant anemia is defined as anemia that occurs within 6 months from the time of transplant. The etiologies include:

1. Postoperative hemorrhage
2. Hemolytic anemia secondary to passenger lymphocyte syndrome or HUS/MAHA
3. Infection including bacterial sepsis or viral infections such as CMV, EBV, or parvovirus
4. Medication, including immunosuppressive drugs and other drugs
5. After renal transplantation, additional causes are iron deficiency or prior uremia or bone disease

Passenger Lymphocyte Syndrome

Passenger lymphocyte syndrome is a graft-versus-host reaction.[268,269] Antibodies made by donor B cells ("passengers") transplanted with the organ are made against host RBCs. This direct antiglobulin-positive immune hemolytic anemia occurs within 3 to 24 days after transplant. Rh antibodies, especially anti-D, are the most common type of antibody. The anemia can be mild to severe but is self-limited, lasting about 1 month. The incidence of this complication increases as the size of the transplanted organ increases:

	Antibody + (%)	Hemolysis (%)
Kidney	17	9
Liver	40	29
Heart–lung	70	70

The incidence also varies depending on the blood type of the donor and recipient:

– 61% with O donor and A recipient
– 22% with O donor and B recipient
– 17% with AB donor and non-AB recipient

Pediatric cases have been reported after all types of solid organ transplant, and the incidence appears to be the same in children and adults, at least after liver transplantation.

Treatment consists of observation alone if mild and transfusion if severe.[268] When transfusing RBCs, the ABO type of the transfused product should be identical to or compatible with the recipient serum, regardless of donor type. When transfusing platelets or fresh-frozen plasma, the product should be compatible with both the recipient and donor. Empiric therapy used in the management of severe cases includes corticosteroids, plasma exchange, and RBC exchange.

Hemolytic Uremic Syndrome/Microangiopathic Hemolytic Anemia

HUS/MAHA after solid organ transplant has been described most often in adults who have the typical clinical presentation for this disorder.[270-272] The majority of cases have been described in renal transplant recipients (90% of cases reported), but it has been seen with all transplant types. The median time of onset is 30 days after transplant, ranging from 8 days to 9 months,[270] and 80% of cases are within 90 days and 96% within 1 year.[272] After renal transplant for HUS, 23% of patients have a recurrence, but the incidence varies depending on the original type of HUS. When transplant is for diarrhea-associated HUS, the recurrence rate is less than 10%. The incidence increases when the original diagnosis is atypical adult HUS and increases even more with familial HUS (60% recurrence rate). In children transplanted for HUS, there was an 8.8% recurrence rate,[271] although it was 80% for those transplanted for atypical HUS and factor H or I deficiency. However, other genetic abnormalities of the complement system are not associated with this high rate of recurrence. Genetic screening is recommended before transplantation not only to determine risk but to develop posttransplant management plans[273] (see later).

The calcineurin inhibitors cyclosporine A (CsA) and tacrolimus (TAC) have triggered the HUS in all of the nonrenal transplant cases and half of the renal transplant cases. Sirolimus alone and especially in combination with cyclosporin has been associated with development of thrombotic microangiopathy.[274] The possibility of an infectious trigger has been suggested for the development of MAHA.

Treatment consists of discontinuing or decreasing the dose or switching the calcineurin inhibitor. Plasma exchange is an unproven therapy. The outcome for graft survival is 60% for de novo HUS but only about 33% for recurrent HUS. In children transplanted for atypical HUS, especially those with a known high risk genetic mutation, perioperative plasma exchange and the use of the terminal complement inhibitor eculizumab have shown promising efficacy in preventing HUS recurrence.[273] Eculizumab has been approved by the U.S. Food and Drug Administration for the treatment of pediatric and adult patients with atypical HUS.

Late Posttransplant Anemia

Anemia occurring greater than 6 months after transplant is termed late *posttransplant anemia*. Causes of late anemia that are common to all solid organ transplants include:[261-263,265,267]

1. Infection with viruses, particularly EBV and parvovirus, and more rarely, CMV
2. Drug effect caused by myelosuppression, hemolytic anemia, or other drug effects (e.g., trimethoprim–sulfamethoxazole, dapsone)

3. Rejection or PTLD
4. Anemia of chronic disease
5. Iron deficiency
6. Acute renal failure
7. Uncommon or multifactorial

Etiologies of late anemia in the renal transplant setting include: end-stage renal disease or low erythropoietin levels (68% of patients will have levels <2 standard deviation [SD] below the norm).[263] After renal transplant, young children have less anemia than older children and young adults. This may be because of the large donor kidney with higher erythropoietin levels and creatinine clearance relative to the size of the patient.

Immunosuppressant Drugs

There is a wide variation—1% to 53%—in the reported incidence of anemia secondary to ISDs. This variation may be a result of the lack of a specific test for drug-associated anemia and the lack of prospective studies. Indirect evidence for the association, however, is quite strong—that is, the ISD is stopped or changed and the anemia improves. There is a clear association of HUS/MAHA with the ISDs CsA and TAC in the early posttransplant period, but a number of studies have documented the association of late anemia with these agents as well. In a study of children after liver transplant, half of the cases of anemia were attributed to ISD.[261] The diagnosis was usually made by excluding other causes of anemia plus evidence of resolution of the anemia after a change in the ISD dose or switch to an alternative drug (median time for resolution, 4 months).

In a study of children and young adults after cardiothoracic transplantation, approximately 25% of the cases of anemia were attributed to tacrolimus, primarily because no other cause was found.[262] The nadir hemoglobin in these patients was 7.3 to 8.8 g/dL, with reticulocytes from 1.5% to 6.7%. Only one patient had a direct antiglobulin study performed, and the results were negative. Four of five patients with simultaneous anemia and neutropenia recovered counts within 5 weeks of switching to CsA. In another study of 50 pediatric renal transplant patients, the prevalence of anemia was 60%, with 30% having hemoglobin levels below 10 g/dL. The TAC dose was found to be significantly associated with the presence of anemia.[275]

The association of PRCA and TAC was first reported in adults. Two children were reported to develop PRCA while taking TAC 8 and 47 months after liver transplantation.[276] Neither had evidence of parvovirus B19 infection. When there was no evidence of spontaneous recovery after 2 to 3 months of observation, they were switched from TAC to CsA, and both recovered within 3 weeks. Of interest, in a study of adults after liver transplantation, erythropoietin production was found to be reduced in patients receiving cyclosporin but not tacrolimus.[277]

There are a number of case reports of AIHA associated with the use of TAC and other ISDs in both children and adults. AIHA has been seen after liver, small bowel, multivisceral, kidney, and heart transplants. Onset of severe anemia has been from 2 months to many years after transplant. The direct antiglobulin test has revealed warm, mixed, or cold antibodies. The common finding in all cases was use of tacrolimus immunosuppression, although in a few cases, other ISDs were also used. Treatment was variable, including corticosteroids, IVIG, plasmapheresis, rituximab, and splenomegaly. TAC was discontinued in many cases with alternative ISD, including cyclosporine or sirolimus initiated. Resolution of the AIHA was the usual outcome with some rapid and apparently sustained responses to rituximab and switching to an alternative ISD.[278-282]

Nonimmune hemolysis has also been documented in adults. In a retrospective study of 81 patients (median age, 39 years; range, 12-66 years) after lung transplantation, 20% developed hemolytic anemia in the first year after transplant.[283] All were taking CsA, and none received TAC. The anemia was mild to moderate, there was no evidence of autoantibody formation or MAHA, and other causes of anemia were excluded. The authors postulate an auto- or alloimmune mechanism to explain this phenomenon.

Anemia has been reported to be associated with all of the currently used ISDs, including mycophenolate mofetil (MMF) and sirolimus. Although direct comparison of all of the drugs has not been performed, it appears that TAC and CsA have a similar incidence,[284] with anemia occurring less commonly with the others. One possible mechanism of the development of autoimmune antibodies posttransplant is the chronic T-cell suppression resulting from the use of these agents followed by release of B-cell control. As noted earlier, treatment has been empiric and has included the standard treatments for AIHA, including rituximab. Reduction in dose or switching the type of the ISD appears to be an effective therapy.

Pure Red Blood Cell Aplasia Associated With Parvovirus B19

Pure RBC aplasia was initially reported in adults in 1986 with multiple reports since that time. Review of the literature in 2006 revealed 91 cases of parvovirus B19 infection posttransplant reported in adults.[283] Seventy-four were in solid organ recipients, with the majority after kidney transplant (71%) followed by heart–lung transplant (16%) and then liver transplant (12%). A total of 99% were anemic, with one-third also having leukopenia and 18% thrombocytopenia. The average time to onset was 1.75 months posttransplant with a range of 1 week to 96 months. The most reliable test to diagnose infection was the parvovirus B19 PCR, with results being positive in 85% of cases; IgM results were positive in 78% and IgG in 39%. Treatment with IVIG was used in 84% of patients, and there was a recurrence in 28%. The three deaths were only seen in patients after liver transplant who developed myocarditis and cardiogenic shock. Of interest, in a prospective study of 47 solid organ transplant recipients, none were found to have molecular evidence of parvovirus B19 in the first year posttransplant.[285]

In a review of parvovirus B19 infection in children after transplantation, there were 16 case reports: five after liver, heart, and renal transplant each and one after bone marrow transplantation.[286] The onset was at a median of 8 months with a range of 1 to 24 months. Although only three of 14 tested were IgM positive, all were PCR positive. There were no associated symptoms in seven of 14, but other reported symptoms include cytopenias, rash, myocarditis, and pneumonia. All 10 patients who received IVIG treatment were cured, although recurrences have been reported.

Platelets

Problems with platelets including thrombocytopenia and thrombocytopathy have been reported after transplant primarily in adults. After liver transplantation, almost all patients develop a transient thrombocytopenia. Delayed thrombocytopenia is much less frequent. It has been reported in 12% of children after liver transplant,[261] 8% after cardiothoracic transplant,[259] and outside of the setting of HUS/MAHA very infrequently after kidney transplantation. Causes of platelet problems posttransplant include medication effect, immune etiology, HUS/MAHA, infection, and other miscellaneous causes.

Immediate Thrombocytopenia After Liver Transplantation

More than 90% of adults have been reported to have thrombocytopenia within the first week after liver transplantation.[287-291] Nadir counts usually occur between days 4 and 6 posttransplant, with an average count of 58,000/μL (range, 19,000-330,000/μL). An increase in thrombopoietin is seen on days 4 to 6, and increased reticulated platelets are noted on days 7 and 8. There are few reported clinical sequelae from the mild thrombocytopenia, although the

lowest platelet counts have been associated with the most severe and complicated posttransplant course. Resolution is usually seen in 2 weeks. Lack of resolution is associated with a poor prognosis for graft and overall survival.

There is controversy regarding the etiology of this transient thrombocytopenia. One theory is that it is a nonimmune consumptive process reflected by increased markers of thrombin generation.[291] The liver may be the site of platelet sequestration. A second theory is that it is unlikely to be a consumptive process because of the lack of platelet activation after day 1. The thrombocytopenia is more likely a result of low levels of thrombopoietin seen pretransplant. With new production and rising levels of thrombopoietin from the new liver, there is a subsequent increase in platelet production, resulting in normalization of the platelet count soon after transplantation. Although the specific etiology has not been clarified, there is general consensus that it is not immune mediated.

Lymphocyte-depleting antibodies such as rabbit antithymocyte globulin (rATG) are being used with increasing frequency as induction type therapy in pediatric liver and intestine transplantation. rATG does exacerbate the transient thrombocytopenia seen immediately after solid organ transplant but resolves in a similar 1- to 2-week period. Treatment of this transient thrombocytopenia is supportive. Platelet transfusions are of uncertain benefit. Although originally azathioprine was believed to be a cause of this thrombocytopenia, there is no evidence that alteration of azathioprine dose is necessary.

Delayed Posttransplantation Thrombocytopenia

Delayed thrombocytopenia is not a major problem after solid organ transplantation, and most of the data are published in adult series. In one retrospective study of 36 adult liver transplant recipients, mild thrombocytopenia (<140,000/μL) was seen in 54% of patients at 1 year and 25% at 3 years after transplant.[292] However, severe thrombocytopenia (<50,000/μL) was only seen in 9% of patients at 1 year and in no patients at 3 years after transplant. The thrombocytopenia was associated with splenomegaly in some patients. No clinical bleeding problems were noted after 1 year from transplant. In one report, three of 25 (12%) pediatric liver transplant recipients were found to have isolated thrombocytopenia.[261] The etiology of the thrombocytopenia in these children was cavernous transformation of the portal vein, autoimmune, and unknown. In two other children in this series, thrombocytopenia was associated with additional cytopenias, and the cause was possibly related to TAC. In an additional study of 126 children who underwent cardiothoracic transplantation, nine (8%) were noted to have isolated thrombocytopenia. Infection was the most common etiology (262). In patients with combined cytopenias, including thrombocytopenia, two-thirds were related to either infection or PTLD and 20% possibly secondary to TAC.

Sirolimus has been associated with mild thrombocytopenia in adults, although the reported frequency has varied. In a study of renal transplant recipients, 23% were reported to have mild thrombocytopenia,[293] but no liver transplant patients taking the drug were found to be thrombocytopenic.[294] In 66 pediatric kidney transplant recipients taking sirolimus, there were no reported cases of thrombocytopenia.[295] Low platelet counts are usually seen within the first 4 weeks of treatment and are associated with higher sirolimus blood levels.[296,297] Similar to TAC and CsA, sirolimus has been shown to potentiate agonist-induced platelet aggregation, although this is not the proven explanation for the thrombocytopenia.[298] A 25% to 50% dose reduction is often effective in resolving sirolimus-mediated thrombocytopenia.

Immune-Mediated Thrombocytopenia Posttransplantation

There are many case reports of immune-mediated thrombocytopenia after all types of solid organ transplantation in children and adults and either alone or in combination with other cytopenias. Eight adults after liver transplant were reported to have immune thrombocytopenia (incidence, 0.7%).[299] The low platelets were seen on average 53 months after transplantation with a range of 1.9 to 173 months. Three patients had demonstrable antiplatelet antibodies. Steroids provided effective therapy in four and rituximab in four, although splenectomy was ultimately necessary in three. Seven of the eight survived with normal platelet counts. Five children were reported to have severe thrombocytopenia (<10,000/μL) within 2 to 4 months after starting TAC.[280,300] All were documented to have antiplatelet antibodies. Responses were seen to steroids, rituximab, or anti-D.

After heart or lung transplantation, two cases in adults have been reported.[301] These cases occurred 60 to 460 days after transplant and responded to prednisone and IVIG. Acquired Glanzmann thromboasthenia has been reported in two children after cardiac transplantation.[281,302] Both were receiving TAC and had demonstrable antibodies against glycoprotein IIb/IIIa. One patient had multiple autoantibodies, and the other subsequently developed additional antiplatelet antibodies. One child responded to prednisone therapy and switching from TAC to CsA. The other responded to rituximab after failing prednisone and IVIG.

Alloimmune thrombocytopenia was reported in three recipients of organs from the same donor (two kidneys and a liver).[303] Development of HPA-1a (PL^{A1}) antibodies from donor B cells were documented in an example of passenger lymphocyte syndrome. The thrombocytopenia in these cases was particularly refractory to standard treatment except transfusion of HPA-1a–negative platelets. One patient died, another required splenectomy, and one patient's thrombocytopenia resolved after an episode of severe graft rejection (see box on Treatment of Immune-Mediated Thrombocytopenia After Solid Organ Transplantation in Children).

Treatment of Immune-Mediated Thrombocytopenia After Solid Organ Transplantation in Children

There is no standard approach to the treatment of immune-mediated thrombocytopenia that occurs after solid organ transplantation. First, all other causes of thrombocytopenia should be ruled out before beginning therapy for what is often a presumptive diagnosis of immune-mediated thrombocytopenia. If the thrombocytopenia is mild to moderate (>20,000-30,000/μL) with no associated bleeding symptoms, we usually observe without intervention and monitor the platelet count on at least a weekly basis. If the platelet count is lower than 10,000 to 15,000/μL or if there is bleeding, immediate treatment is initiated with high-dose corticosteroids: 4 mg/kg/day of prednisone (or intravenous equivalent) divided in three or four doses and continued for 4 days. If there is a response (i.e., platelet count >20,000/μL), the corticosteroid is dropped to 2 mg/kg/day divided in two or three doses and then slowly tapered to zero over the subsequent 2 to 3 weeks. IVIG or anti-D in standard doses used for childhood ITP can be used if there is no response to high-dose corticosteroids.

For patients who have recurrent or chronic thrombocytopenia requiring multiple courses of treatment to maintain platelet counts greater than 10,000 to 15,000/μL, we have used vincristine (1.5 mg/M^2 [maximum dose, 2 mg] intravenously weekly for 6 weeks) with success. Rituximab (375 mg/M^2 IV weekly for 4 weeks) has infrequently been used in this situation. For patients taking tacrolimus with refractory thrombocytopenia, serious consideration should be given to switching to an alternative ISD because this may be necessary for resolution of the thrombocytopenia. Involvement of both the transplant team and the hematology team is necessary for ideal management of these complex patients.

Infection-Associated Thrombocytopenia Posttransplantation

Although there are few published reports, one would expect the same hematologic problems, including thrombocytopenia, associated with bacterial sepsis or other serious infections as seen in nontransplant patients. Infection with HHV-6 and the herpesvirus group has been studied closely. HHV-6 is commonly seen after transplant, mostly in stem cell transplant recipients. In adults after liver transplant, there are case reports of a syndrome of HHV-6 infection with thrombocytopenia, fever, and encephalopathy.[304] This syndrome has not been reported in children with HHV-6 infection.[305,306]

Herpesvirus infection after kidney transplantation in children is seen in about one-third of patients, with CMV being the most common infection.[307] The hematologic abnormalities associated with herpesvirus infection include thrombocytopenia and leukopenia, with an incidence of 31% and 24%, respectively. These and other symptoms of herpesvirus infection occur at the same frequency as nontransplant patients.

There is a case report of a child after liver transplant who developed measles complicated by autoimmune thrombocytopenia and neutropenia.[308]

White Blood Cells

Leukopenia and neutropenia are uncommonly reported in the literature after solid organ transplantation, although this may not reflect the true incidence seen in practice.[309] In two reviews of hematologic complications in children after transplantation, isolated neutropenia was seen in two of 70 (3%) patients after liver transplant and nine of 106 (8%) patients after cardiothoracic transplant.[261,262] Neutropenia was also seen in combination with other cytopenias. Although there are predominantly case reports in the pediatric literature, in one review of neutropenia after 400 renal transplants in adults, 35 cases (9%) were reported.[310] The etiology of leukopenia or neutropenia is similar in children and adults and includes immunosuppressive agents; other myelosuppressive drugs (e.g., ganciclovir); infection (e.g., CMV, sepsis); and less frequently, INF, PTLD, hypersplenism, INF, and idiopathic. Use of TAC is often implicated as a possible contributing factor.

Both filgrastim (granulocyte colony-stimulating factor) and sargramostim (granulocyte macrophage colony-stimulating factor) have been used to treat neutropenia in adults and children. In adults, it has resulted in improvement of the WBC count in more than 90% of patients after three to four doses.[310,311] There was no evidence of precipitation of rejection. In the case reports in children, both agents have been found to be effective in most patients, but there is a suggestion that efficacy may be affected by continuation of TAC.[309,312,313] Although cytokine therapy has been shown to increase the neutrophil count, there are insufficient data to prove effectiveness of preventing or treating infection or decreasing mortality.[314]

There has been one report on the use of granulocyte transfusions in solid organ transplant recipient, including one child. Of the 14 patients studied, 11 showed an increase in ANC greater than 1000/μL by the end of the course. Of 12 patients with infections, four (33%) showed a clinical response. Additional studies will be needed to evaluate the efficacy of granulocyte transfusions in transplant patients.[314]

Azathioprine is well known to cause myelosuppression and has been associated with moderate to severe neutropenia. Azathioprine is catabolized in vivo by xanthine oxidase and thiopurine methyltransferase (TPMT). TPMT activity can vary considerably depending on a genetic polymorphism. Approximately 0.3% of whites are homozygous and 11% heterozygous for deficiency of TPMT. Severe myelosuppression, including fatal neutropenia, has been documented in transplant patients who are homozygous for TMPT deficiency and receiving azathioprine.[315] Some data suggest that monitoring 6-thioguanine nucleotides (the metabolites of azathioprine) may allow for individualized management of azathioprine dosing with fewer side effects, although this has not become common practice.[316,317]

Neutropenia has also been associated with the use of MMF and sirolimus. Neutropenia and thrombocytopenia have been noted as side effects of MMF since 1998.[318] Leukopenia may affect 5% to 11% of patients taking the drug, and pseudo Pelger-Huet anomaly has also been noted.[319,320] The leukopenia is often seen within 2 to 8 months after starting the drug. Filgrastim has been effective in reversing the neutropenia, although some patients required decreasing the dose or stopping the drug. Ganciclovir and valacyclovir are commonly used simultaneously with MMF to treat or prevent CMV disease. These drugs are also known to be associated with neutropenia.[321] There may be an interaction between these drugs that increases the risk for neutropenia.[322,323] It may be necessary to stop ganciclovir as well as MMF for the neutropenia to improve.[319] Of note, serious infections are infrequently encountered.

In two reports of the use of sirolimus in children, neutropenia was the most common toxicity along with hepatitis, hyperlipidemia, and mouth ulcers.[324,325] It is not clear whether the neutropenia is directly related to serum level of the drug. Most counts improve with a decrease in the drug dose, although a few patients need to have the drug discontinued.

Pancytopenia

Pancytopenia is seen in two settings after solid organ transplantation. The first is early after liver transplant for acute liver failure from acute infectious hepatitis.[326,327] This represents the known aplastic anemia that can be seen in as many as one-third of patients after non-A-E hepatitis. Treatment and outcome are similar to those in patients with posthepatitic aplastic anemia who do not require liver transplantation. The second setting is delayed pancytopenia, which may be secondary to infection with or without PTLD.[328] A number of cases have been associated with the use of TAC.[261,329] Hemophagocytic syndrome has also been reported in the posttransplant setting, usually caused by an acquired viral infection.[330]

HEMATOLOGIC ASPECTS OF POISONING

It has been estimated that about 6 million children, most younger than 5 years of age, ingest some toxin each year. The effects of toxins on the blood are diverse, usually nonspecific, and in most situations overshadowed by the nonhematologic manifestations of the exposure.[331] With certain toxins, however, bleeding, anemia, or change in the appearance (color) of the blood may be an important component of the clinical sequelae of an acute exposure.

The abnormalities of hemostasis after poisoning are numerous, and the mechanisms vary. Bleeding may be the only manifestation of warfarin toxicity secondary to an overdose of the drug or ingestion of a rodenticide containing warfarin. Any hepatotoxic substance (e.g., iron, acetaminophen) may lead to decreased synthesis of clotting factors and resultant coagulopathy. Bleeding in these circumstances is delayed for at least 24 hours, although there appears to be an early coagulopathy in iron poisoning that may be caused by a direct effect on clotting protein function and not hepatotoxicity.[332] DIC has been seen after ingestion of mushrooms of the *Amanita* genus or after a bite from the brown recluse spider *(Loxosceles reclusa).* Poisonous snake bites can result in coagulation abnormalities characterized by hypofibrinogenemia with or without thrombocytopenia or a DIC-like syndrome.[331] Severe thrombocytopenia has been described with elemental mercury poisoning.

Acute hemolytic anemia may be the presenting manifestation after exposure to drugs and toxins in children with G6PD deficiency or hemoglobin Zürich or (rarely) in normal children. Severe hemolytic anemia has been seen after the bite of the brown recluse spider and of a rattlesnake and after a wasp sting.

Exposure to certain toxins may result in characteristic color changes of the blood, which in turn may be reflected clinically in abnormal skin color. The child with methemoglobinemia (see next paragraph) presents with a slate-gray cyanosis unresponsive to 100%

oxygen administration. On exposure to air, the blood retains a distinct brown color. Patients with toxic exposure to carbon monoxide or cyanide have increased levels of carboxyhemoglobin or cyanhemoglobin, respectively, resulting in a cherry-red color of the blood and skin, but only with high concentrations of the offending hemoglobin.

Infants (up to 4 months of age) are at particular risk for developing methemoglobinemia because of a reduced amount (≈60% of normal) of cytochrome b5 reductase present in neonatal RBCs. Methemoglobinemia has been described in infants with diarrheal illness and in infants exposed to exogenous agents.[333]

Yano and colleagues[334] described 11 patients with transient methemoglobinemia, all infants younger than 1 month of age, who presented with vomiting, diarrhea, and acidosis. In prospective studies of infants younger than 6 months of age with diarrheal disease, 64% had elevated levels of methemoglobin (with a mean ± SD of 10.5% ± 12.3%), 31% were cyanotic, most infants were small or failing to thrive, there was no association of methemoglobinemia and acidosis, and all children recovered from their illness.[335,336] Although most infants with endogenous methemoglobinemia can be managed with support and hydration, treatment with methylene blue (1 mg/kg) is indicated in symptomatic or more severely affected children (i.e., with methemoglobin >20%-30%).

Nursery epidemics of methemoglobinemia have been reported in normal newborns exposed to disinfectants or aniline dyes used to mark diapers. Infants fed formulas made with well water containing a high concentration of nitrates have developed methemoglobinemia. EMLA cream, a eutectic mixture of the local anesthetics lidocaine and prilocaine, has been effective in decreasing pain in infants undergoing circumcision. Methemoglobinemia has been reported with EMLA use in this situation but only in overdose.[337] Other ingestions associated with methemoglobinemia include phenazopyridine (Pyridium), dapsone, metoclopramide, and nitroethane (an artificial fingernail remover). Although the list of oxidants reported to cause methemoglobinemia is long, methemoglobinemia caused by exogenous agents is uncommonly seen in infants and children.[338]

Lead Poisoning

Lead poisoning in children has been a serious public health problem for decades. However, the most serious toxic effects of lead (e.g., encephalopathy) commonly seen in the past are rarely encountered today, primarily because of measures instituted to decrease lead exposure (no-lead paint, no-lead gasoline) and screening programs in high-risk areas. Mean blood lead levels in the United States have declined, from 15 μg/dL between 1976 and 1982 to 3.6 μg/dL between 1988 and 1991.[328] Nonetheless, lead toxicity remains a problem, especially in high-risk children. Additionally, children arriving from other countries with less stringent public health requirements regarding lead exposure remain at risk for significant lead toxicity.[339] Increasing evidence shows that even low levels of lead exposure are associated with a significant decline in neurodevelopmental outcome, and in 1991, the Centers for Disease Control and Prevention (CDC) lowered the intervention level of lead in the blood from 25 to 10 μg/dL.[339,340] Reviews of the public health issues relating to lead poisoning in children have been published.[341]

The occurrence of lead poisoning in children with sickle cell disease may be underrecognized. Pica may be a manifestation of sickle cell anemia, even in the absence of iron deficiency, predisposing children to lead ingestion.[342] Additionally, some children with sickle cell disease may be at risk for environmental lead exposure, including substandard housing with lead paint. The signs and symptoms of lead toxicity may resemble those of sickle cell disease, including abdominal pain, peripheral neuropathy with extremity pain, constipation, and hyponatremia.[343] Lead toxicity should be considered in the differential diagnosis of children with unusual manifestations of sickle cell disease.

The primary hematologic effect of lead is interference at multiple points along the heme synthetic pathway. The two most important effects are inhibition of δ-aminolevulinic acid (ALA) dehydratase and ferrochelatase, resulting in the accumulation of heme intermediates such as protoporphyrin. A shortened RBC survival time accompanies lead poisoning and probably is caused by decreased activity of pyrimidine 5-nucleotidase (also resulting in basophilic stippling of the RBC) and possibly inhibition of G6PD and the pentose shunt.[344]

The anemia of lead poisoning has classically been described as a hypochromic, microcytic anemia, as might be expected from the effects of lead on heme synthesis. Although anemia has been said to be a common finding in lead intoxication, in reality, anemia is uncommon unless the lead poisoning is severe or there is associated iron deficiency.

A strong association exists between lead poisoning and iron deficiency in children. Both tend to occur in the same population of predominantly lower socioeconomic status. Experimentally, iron deficiency has been shown to increase lead absorption, retention in tissues, and toxicity. Iron deficiency also decreases lead excretion during chelation.[345] Lead may impede iron absorption and metabolism, leading to a vicious circle of increasing lead toxicity and worsening iron deficiency. In a study of children with lead poisoning (blood lead ≥30 μg/dL), 86% were found to have iron deficiency, and 100% of those with more severe lead poisoning (CDC risk classification III) were iron deficient.[346]

A number of reports in children with lead toxicity have documented the infrequent occurrence of anemia without concomitant iron deficiency. Cohen and colleagues[346] found anemia in 12% and microcytosis in 21% of iron-sufficient children with severe lead poisoning (CDC classes III and IV). The combination of anemia plus microcytosis, however, was found in only one of the 58 children in their series. In less severely affected children (CDC classes I to III), Yip and associates[347] found a 30% incidence of anemia, but of those with either mild or no iron deficiency, only 6% were anemic. Clark and coworkers,[348] using multiple linear regression analysis, found transferrin saturation to be the most important predictor of mean corpuscular volume, hemoglobin, and zinc protoporphyrin levels in children with lead poisoning.

Two important points emerge from the foregoing information: (1) children with significant lead poisoning may have neither anemia nor microcytosis, and (2) children with documented lead poisoning should be screened for underlying iron deficiency. The immediate treatment and long-term management of patients with lead poisoning can be found in a recent review.[349]

HEMATOLOGIC ASPECTS OF METABOLIC DISEASES

A number of congenital disorders of metabolism may manifest hematologic abnormalities as part of the clinical presentation. Such global metabolic defects have diverse manifestations; especially prominent are neurologic abnormalities, failure to thrive, and unexplained metabolic acidosis. Although the hematologic findings may be overshadowed by the systemic illness, the recognition of a characteristic pattern of signs and symptoms may lead expeditiously to the correct diagnosis. Table 154-4 is a compilation of inborn disorders of metabolism that may manifest in infancy or childhood with hematologic cytopenias.[350] Additional information regarding metabolic disorders is available through the Online Mendelian Inheritance in Man (http://www.ncib.nlm.nih.gov/omim).

SPLENOMEGALY IN CHILDREN

Splenomegaly is a problem frequently encountered by both pediatricians and pediatric hematologists. Although the spleen is rarely a site of primary disease, it may reflect systemic involvement in a variety of disorders. The spleen is the largest collection of lymphoid tissue in the body, with a unique association between the bloodstream and the reticuloendothelial compartment of the spleen. Splenomegaly may result when there is antigenic stimulation of the lymphoid

Table 154-4 Hematologic Manifestations of Metabolic Disease With Onset in Infancy and Childhood

Category	Disease	Defect	Hematologic Finding(s)	Associated Findings
Lysosomal enzyme defects	Gaucher disease, type 1	Glucocerebrosidase deficiency	Anemia, thrombocytopenia	Splenomegaly, bone abnormalities, delayed puberty, lipid engorged macrophages (Gaucher cell) in BM
	Niemann-Pick disease, type A	Acid sphingomyelinase deficiency	Anemia	Feeding difficulties, hepatosplenomegaly, developmental delay, neurodegenerative course, cherry-red macula, lipid-laden macrophages (foam cells) in BM
	Wolman disease	Acid lipase deficiency	Anemia, thrombocytopenia	Emesis, diarrhea, hepatosplenomegaly, vacuolization of lymphocytes, lipid-laden macrophages in BM, adrenal calcification
	Aspartylglycosaminuria	Aspartylglycosaminidase deficiency	Neutropenia	Recurrent infections, diarrhea, hernias, lens opacities, neurologic abnormalities, vacuolated lymphocytes
Defects of heme synthesis	Congenital erythropoietic porphyria	Uroporphyrinogen III cosynthase deficiency	Anemia, thrombocytopenia	Hemolysis, staining of diapers, photosensitivity, developmental delay, splenomegaly, erythrodontia
	Erythropoietic protoporphyria	Ferrochelatase deficiency	Anemia, thrombocytopenia	Hemolysis, photosensitivity, neurologic abnormalities, hepatobiliary dysfunction
Defect of amino acid metabolism	Tyrosinemia, type 1	Fumarylacetoacetate hydrolase deficiency	Anemia, thrombocytopenia	Failure to thrive, emesis, hepatopathy, neurologic abnormalities, bleeding, "cabbage-like" odor, renal tubular dysfunction
Defects of organic acid metabolism	Isovaleric academia	Isovaleryl-CoA dehydrogenase deficiency	Anemia, thrombocytopenia, neutropenia, pancytopenia	Acidosis, emesis, neurologic abnormalities, odor of "sweaty feet"
	Methylmalonic academia	Methylmalonyl-CoA mutase deficiency	Anemia, thrombocytopenia, leukopenia, pancytopenia	Acidosis, neurologic abnormalities, failure to thrive, emesis
	Mevalonic aciduria	Mevalonate kinase deficiency	Anemia, thrombocytopenia	Acidosis, cataracts, neurologic abnormalities, hepatosplenomegaly
Defects of organic acid metabolism	Propionic academia	Propionyl CoA carboxylase deficiency	Anemia, thrombocytopenia neutropenia, pancytopenia	Ketotic hyperglycinemia, acidosis, neurologic abnormalities
	Pyroglutamic aciduria	Glutathione synthetase deficiency	Anemia, neutropenia	Hemolysis, neurologic abnormalities, metabolic acidosis
Membrane transport defect	Lysinuric protein intolerance	*SLC7A7* gene mutations	Anemia, thrombocytopenia, leukopenia, pancytopenia	Malabsorption, protein intolerance, hyperammonemia, neurologic abnormalities, glomerulonephritis, pulmonary hemorrhage, hemophagocytosis
Glycolytic pathway defects	Triosephosphate isomerase deficiency	Triosephosphate isomerase deficiency	Anemia	Hemolysis, neurologic abnormalities, myopathy
	Phosphoglycerate kinase deficiency	Phosphoglycerate kinase deficiency	Anemia	Hemolysis, neurologic abnormalities
Defects of vitamin metabolism	Cobalamin metabolic defects	Cobalamin transport and utilization defects	Anemia, thrombocytopenia, neutropenia, pancytopenia	Megaloblastosis, failure to thrive, neurologic abnormalities
	Folate metabolic defects	Folate transport and utilization defects	Anemia, thrombocytopenia	Megaloblastosis, ringed sideroblasts, diarrhea, failure to thrive, neurologic abnormalities
	Holocarboxylase synthetase deficiency	Holocarboxylase synthetase deficiency	Thrombocytopenia	Acidosis, hyperammonemia, respiratory distress, neurologic abnormalities, skin rash
Defect in metal metabolism	Wilson disease	*ATP7B* gene mutation	Anemia	Hemolysis, liver dysfunction, neurologic abnormalities, Kayser-Fleischer rings, arthropathy
Defects of purine and pyrimidine metabolism	Hereditary orotic aciduria synthase deficiency	Uridine-5′-monophosphate	Anemia, leukopenia	Megaloblastosis, orotic acid crystalluria, immunodeficiency
	Lesch-Nyhan syndrome	Hypoxanthine-guanine phosphoribosyltransferase deficiency	Anemia	Megaloblastosis, hyperuricemia, nephrolithiasis, neurologic abnormalities, self-mutilation

Continued

Table 154-4 Hematologic Manifestations of Metabolic Disease With Onset in Infancy and Childhood—cont'd

Category	Disease	Defect	Hematologic Finding(s)	Associated Findings
Defects of carbohydrate metabolism	Galactosemia	Galactose-1 phosphate uridyltransferase deficiency	Anemia	Hemolysis, failure to thrive, neurologic findings, jaundice, emesis, diarrhea, hepatic dysfunction, cataracts, gram-negative sepsis
	Glycogen storage disease type 1b	Deficient hepatic transport of glucose-phosphate	Anemia, neutropenia	Hypoglycemia, acidosis, hepatomegaly, xanthomas, inflammatory bowel disease
	Hereditary fructose intolerance	Aldolase B deficiency	Anemia, thrombocytopenia	Poor feeding, emesis, failure to thrive, neurologic findings, hypoglycemia, liver dysfunction, ringed sideroblasts, coagulopathy, hemophagocytosis, shock
Mitochondrial disorders	DIDMOAD syndrome (Wolfram syndrome)	Mitochondrial DNA deletion	Anemia, thrombocytopenia, neutropenia, pancytopenia	Megaloblastosis, ringed sideroblasts, diabetes insipidus, diabetes mellitus, optic atrophy, deafness
	Pearson syndrome	Mitochondrial DNA deletions	Anemia thrombocytopenia, neutropenia, pancytopenia	Ringed sideroblasts, vacuolization of BM precursors, exocrine pancreatic dysfunction, metabolic acidosis
Lipoprotein disorder	Abetalipoproteinemia	Microsomal triglyceride transfer protein defects	Anemia	Hemolysis, acanthocytosis, bleeding, emesis, diarrhea, failure to thrive, neurologic findings
Miscellaneous disorders	Barth syndrome (endocardial fibroelastosis-2)	Tafazzin gene mutations	Neutropenia	Cardiomyopathy, endocardial fibroelastosis, skeletal myopathy, short stature, 3-myethylglutaconicaciduria, abnormal mitochondria
	Cyclic hematopoiesis	Neutrophil elastase gene mutation	Neutropenia	Recurrent oral ulcers, poor dentition, recurrent fever, malaise
	Severe congenital neutropenia (Kostmann syndrome)	Neutrophil elastase gene mutation	Neutropenia	Severe invasive infections, acute leukemia
	Wiscott-Aldrich syndrome	*WAS* gene mutations	Thrombocytopenia	Eczema, infections, small platelets

BM, Bone marrow; *CoA,* coenzyme A; *DIDMOAD,* diabetes insipidus, diabetes mellitus, optic atrophy, deafness.

Evaluation and Management of Children With Splenomegaly

When evaluating a child with chronic splenomegaly, the clinician must consider all of the possibilities noted in Table 154-5. Clues from the history and physical examination may suggest a specific etiology and direct a tailored approach to the diagnostic laboratory evaluation. If, on the other hand, there is no apparent cause of the enlarged spleen, a number of screening laboratory tests should be performed, including a complete blood count with differential, platelet count, and reticulocyte count; evaluation of the peripheral smear; determination of sedimentation rate; liver function tests; determination of antibody titers to EBV, CMV, and *Toxoplasma* spp.; antinuclear antibody assay; and ultrasound evaluation of the liver, spleen, and portal system (the last with Doppler flow technique). Further evaluation, including bone marrow examination, may be necessary if the screening tests do not reveal the cause of the splenic enlargement.

Management of splenomegaly usually is that of the underlying disease, when such treatment exists. Splenectomy may be indicated in selected conditions, but the potential benefits from splenectomy must be weighed against the risk of postsplenectomy sepsis, a rapidly progressive bacteremia, most commonly from *S. pneumoniae,* with a mortality rate of approximately 50%. The risk of postsplenectomy sepsis depends on the age of the patient and the nature of the underlying disorder. Patients younger than 3 years of age and those with a compromised immune or reticuloendothelial system are most susceptible. When elective splenectomy is indicated, it is advisable to (1) postpone surgery until the patient is at least 5 to 6 years of age; (2) administer pneumococcal, meningococcal, and *H. influenzae* vaccines (if the patient was not previously immunized) at least 1 to 2 weeks before splenectomy; (3) consider use of prophylactic penicillin for at least 4 years; and (4) manage significant febrile illnesses as possible postsplenectomy sepsis at all times. In addition to the risk of postsplenectomy sepsis, the rare complication of postsplenectomy portal or splenic vein thrombosis must also be considered.

For children younger than 5 years of age with severe symptoms from hemolytic anemia, hemoglobinopathy, or hypersplenism, partial splenectomy should be considered. In a number of studies, up to 90% of the spleen has been removed safely, with a high rate of success and preservation of splenic function.[351,352] Regrowth of the spleen to variable degrees has been noted, with occasional need for reoperation.

Table 154-5 Causes of Splenomegaly in Children

DISORDERS OF THE BLOOD
Hemolytic anemia: congenital or acquired
Thalassemia
Sickle cell disease
Leukemia
Osteopetrosis
Myelofibrosis, myeloid metaplasia, thrombocythemia
INFECTIONS: ACUTE AND CHRONIC
Viral
Congenital (e.g., TORCH association)
Mononucleosis (e.g., EBV, CMV infection)
Virus-associated hemophagocytic syndrome
Human immunodeficiency virus
Bacterial
Sepsis or abscess
Brucellosis
Salmonellosis
Tularemia
Tuberculosis
Subacute bacterial endocarditis
Syphilis
Lyme disease
Fungal
Histoplasmosis (disseminated)
Rickettsial
Rocky Mountain spotted fever
Cat scratch disease
Parasitic
Toxoplasmosis
Malaria
Leishmaniasis (kala-azar)
Schistosomiasis
Echinococcosis
HEPATIC AND PORTAL SYSTEM DISORDERS
Acute or chronic active hepatitis
Cirrhosis, hepatic fibrosis, biliary atresia
Portal or splenic venous obstruction (Banti syndrome)
AUTOIMMUNE DISEASE
Juvenile rheumatoid arthritis
Systemic lupus erythematosus
Autoimmune lymphoproliferative syndrome (Canale-Smith syndrome)
NEOPLASMS AND CYSTS
Lymphomas (Hodgkin and non-Hodgkin)
Hemangiomas and lymphangiomas
Hamartomas
Congenital or acquired (posttraumatic) cysts
STORAGE DISEASES AND INBORN ERRORS OF METABOLISM
Lipidoses: Gaucher disease, Niemann-Pick disease, others
Mucopolysaccharidoses
Defects in carbohydrate metabolism: galactosemia, fructose intolerance
Sea-blue histiocyte syndrome
MISCELLANEOUS DISORDERS
Histiocytoses
Reactive
Langerhans cell
Malignant
Sarcoidosis
Congestive heart failure
Familial Mediterranean fever

CMV, Cytomegalovirus; *EBV,* Epstein-Barr virus; *TORCH,* toxoplasmosis, other infections, rubella, cytomegalovirus infection, herpes simplex.

system (e.g., infection), obstruction of blood flow within or distal to the spleen (e.g., portal vein obstruction), exaggeration of one of the normal functions of the spleen because of an underlying abnormality (e.g., hemolytic anemia, splenic sequestration), or infiltration of the spleen by a foreign cell (e.g., leukemia, storage diseases).

The spleen tip normally is palpable in preterm infants; up to 30% of full-term neonates have a palpable spleen. A spleen can be felt in up to 5% to 10% of normal children, but most of these are in the infant or toddler age group. As a general rule, a spleen easily palpable below the costal margin in any child older than the age of 3 to 4 years must be considered abnormal until proven otherwise. That some palpable spleens may indeed be normal is attested to by the study of McIntyre and Ebaugh,[353] who found that 3% of healthy college freshmen have palpable spleens, of which about one-third persist. "Pretenders" of splenomegaly include the left lobe of the liver, a left upper quadrant tumor such as Wilms tumor or neuroblastoma, the "wandering spleen," and the proptotic spleen (seen in children with a depressed diaphragm from obstructive pulmonary disease, such as asthma or bronchiolitis).

The most common cause of acute splenomegaly in children, especially young children, is a viral infection. Splenic enlargement in this setting is mild to moderate and usually transient. When the history and physical findings suggest a viral etiology, a complete blood count with differential, platelet count, and reticulocyte count should be performed to rule out unsuspected leukemia or hemolytic anemia and to determine whether there is an atypical lymphocytosis. The child should be reevaluated in approximately 4 weeks (or sooner if symptoms persist). If splenomegaly persists beyond 4 to 6 weeks, the splenic enlargement may be considered chronic.

A list of causes of splenomegaly in children is presented in Table 154-5.[354] Symptoms from splenic enlargement are uncommon, although massive splenomegaly may cause abdominal discomfort and early satiety. If the spleen is sufficiently large, there may be increased destruction or sequestration of one or more of the formed elements of the blood (hypersplenism). Cytopenias tend to be mild to moderate, with the platelet count affected the most.

An approach to the pediatric patient with splenic enlargement is outlined in the box on Evaluation and Management of Children With Splenomegaly.

CHAPTER 155

HEMATOLOGIC MANIFESTATIONS OF LIVER DISEASE

Andrea Lee and Wendy Lim

From a hematologic perspective, the liver is essential for heme metabolism and extramedullary hematopoiesis, affects the structure of the red blood cell (RBC) membrane through lipid metabolism, and is involved in the production of hematopoietic growth factors such as thrombopoietin. The liver plays a major role in hemostasis through synthesis of coagulation factors, coagulation inhibitors, and fibrinolytic proteins and is involved in the clearance of activated coagulation factors, proteolytic enzyme–inhibitor complexes, fibrin, and fibrinogen degradation products. As a consequence, chronic liver disease is frequently associated with multiple hematologic abnormalities.

Progressive liver disease can lead to cirrhosis, which is often associated with portal hypertension and splenomegaly. Portal hypertension can lead to the formation of portal gastropathy or gastric, esophageal, or rectal varices, resulting in gastrointestinal bleeding. Sequestration of hematopoietic cells caused by splenomegaly may manifest as any combination of leukopenia, thrombocytopenia, and anemia.

This chapter discusses several common hematologic abnormalities encountered in liver disease, including RBC, leukocyte, and platelet abnormalities; coagulopathy; and thrombosis.

RED BLOOD CELL ABNORMALITIES

Morphologic Abnormalities

The size and shape of the RBC membrane can be affected by abnormal lipid metabolism caused by liver disease. Excess cholesterol content of the outer leaflet of the RBC membrane bilayer is thought to be responsible for the common morphologic findings observed, including macrocytosis, target cells, and acanthocytes (spur cells) (Fig. 155-1), and is associated with a loss of RBC membrane fluidity and deformability. When these less deformable RBCs traverse through the splenic microcirculation, cytoskeletal damage and permanent deformation can occur, resulting in the formation of spur cells.[1]

Spur cell anemia is a type of hemolytic anemia, with the most common cause being chronic or severe liver disease.[1] Life-threatening hemolysis can ensue, as well as disseminated intravascular coagulation (DIC), gastrointestinal bleeding, or liver failure depending on the primary cause.[1] Spur cell anemia associated with hereditary diseases such as neuroacanthocytosis syndromes or lipoprotein disorders, however, tends to be milder (see Chapter 45). Treatment options for spur cell anemia associated with liver disease are limited and suboptimal. The most effective therapy is liver transplantation.[2] Clinical improvement using flunarizine, pentoxifylline, and cholestyramine has been documented in case reports.[3]

Anemia

Cytopenias are detected in approximately 75% of patients with liver disease. The etiology of anemia is multifactorial, although gastrointestinal hemorrhage is a primary contributor.[4] Hemodilution can occur due to fluid retention related to cirrhosis. Hypersplenism or splenomegaly results in sequestration of erythrocytes. Reduced erythropoiesis may exist secondary to nutritional deficiencies in folate or vitamin B_{12} resulting from poor intake or malabsorption, bone marrow suppression from alcohol or viral hepatitis, hepatitis-associated aplastic anemia, treatment-related toxicities for viral hepatitis (e.g., interferon), and anemia of chronic disease. Patients with chronic liver disease or cirrhosis can also experience nonimmune hemolysis because of acquired alterations in the RBC membrane (e.g., spur cell anemia), Zieve syndrome, or treatment-related toxicities (e.g., ribavirin).[4]

The therapeutic approach to anemia in liver disease includes transfusional support for symptomatic disease; identification and treatment of any gastrointestinal bleeding; supplementation for documented iron, vitamin B_{12}, or folate deficiencies; discontinuation of bone marrow suppressive medications or alcohol; and appropriate treatment for the primary cause of liver disease.

Small studies have suggested that inadequate production or response to erythropoietin (EPO) also contributes to chronic anemia in hepatic disease, although the association is controversial.[5] Nonetheless, EPO supplementation has demonstrated clinical efficacy, cost-effectiveness, and increased quality of life in patients with hemoglobin less than 12 g/dL undergoing hepatitis C antiviral therapy.[6] The use of EPO to maintain a hemoglobin greater than 10 g/dL may obviate the need for dose reduction or discontinuation of ribavirin, either of which reduce rates of sustained viral response. It may take up to 6 weeks to observe a significant rise in hemoglobin in response to EPO.

WHITE BLOOD CELL ABNORMALITIES

Leukopenia

Leukopenia, particularly neutropenia, has been observed in up to 55% of patients with cirrhosis.[7] Splenic sequestration is considered to be the main culprit; however, reduced production of leukocytes may also be a consequence of altered granulocyte colony-stimulating factor (G-CSF) and granulocyte macrophage colony-stimulating factor (GM-CSF) levels, bone marrow suppression mediated by primary infections or toxins (e.g., hepatitis B or C, alcohol), or an iatrogenic effect from treatment with interferon. Immune-mediated neutropenia can occur in the context of hepatitis C or autoimmune hepatitis, and increased apoptosis may also be responsible for a shortened neutrophil lifespan.[8] Furthermore, impairment in neutrophil recruitment and phagocytic function may contribute to an increased susceptibility for severe and recurrent infections in patients with cirrhosis.[9] G-CSF and GM-CSF have been safely used in patients with cirrhosis and neutropenia in the setting of hypersplenism or treatment of viral hepatitis, resulting in improvements in white blood cell counts. The impact on risk of infection or response to antiviral therapy, however, is unclear.[10,11]

PLATELET ABNORMALITIES

Thrombocytopenia

Thrombocytopenia alone or in combination with other cytopenias is the most common cytopenia associated with liver disease, occurring in up to 77% of patients with cirrhosis.[7] Platelet counts are usually mildly to moderately reduced; severe thrombocytopenia ($<30\text{-}40 \times 10^9$/L) and spontaneous bleeding are uncommon.

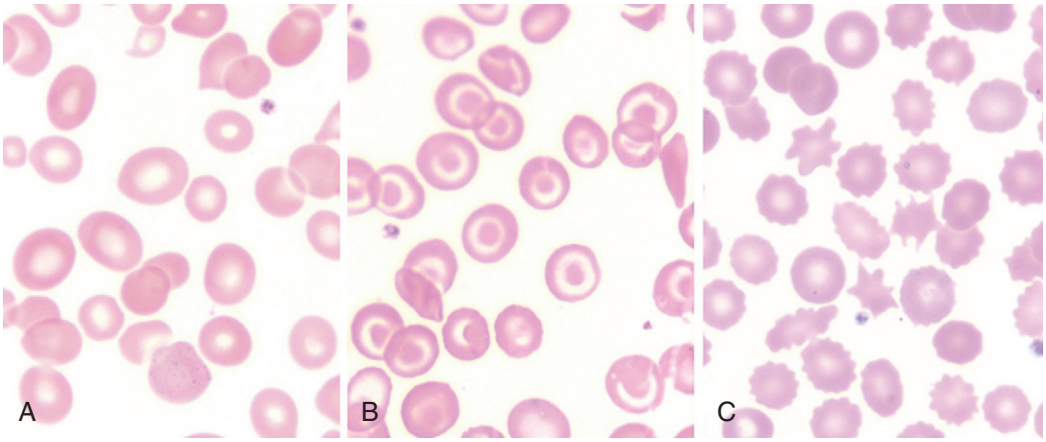

Figure 155-1 RED BLOOD CELL (RBC) MORPHOLOGY IN LIVER DISEASE. **A,** Macrocytes have a mean corpuscular volume greater than 100 fL and can be oval shaped. Commonly associated disorders include liver disease and vitamin B_{12} and folate deficiency. **B,** Target cells are characterized by the bull's-eye appearance of the RBC. They are a result of an increased surface-to-volume ratio related to excess RBC membrane (e.g., liver disease) or disproportionate reduction of cytoplasmic content (e.g., hemoglobinopathies, iron deficiency). **C,** Acanthocytes, or spur cells, typically appear as contracted RBCs lacking central pallor with multiple irregular membrane projections. The morphologic appearance reflects the irreversible cytoskeletal damage that has occurred because of passage of nondeformable RBCs through the reticuloendothelial system. They are most commonly seen in severe liver disease but can also be features of rare neuroacanthocytosis syndromes or lipoprotein disorders.

Many factors contribute to thrombocytopenia in liver disease. Decreased platelet counts may result from splenomegaly and hypersplenism. There may be impaired platelet production in the bone marrow related to nutritional deficiencies in folate or vitamin B_{12}; direct toxicity of alcohol, viral hepatitis, or interferon treatment; or reduced hepatic synthesis of thrombopoietin. Accelerated destruction of platelets can occur via immune-mediated mechanisms because autoantibodies to platelet antigens have been demonstrated in patients with cirrhosis. Although controversial, the presence of low-grade DIC may contribute to platelet consumption.[12] Thrombocytopenia in patients with cirrhosis, especially in combination with leukopenia, has been associated with increased morbidity and mortality.[7]

Platelet Dysfunction

Laboratory evaluation of platelet function has demonstrated abnormal bleeding times (BTs), PFA-100 results, and platelet aggregation in response to multiple agonists in some individuals with liver disease, implying that there may be a component of platelet dysfunction.[12] Intrinsic platelet defects leading to abnormal platelet aggregation or adhesion include impaired transmembrane signaling and thromboxane A2 synthesis, storage pool deficiency, or defects in platelet glycoprotein Ib or $\alpha_{IIb}\beta_3$ receptors.[12] Extrinsic defects resulting in platelet dysfunction include circulating fibrin(ogen) degradation products, bile salts, abnormal high-density lipoproteins, reduced hematocrit, and excess production of nitric oxide and prostacyclin.[12]

The clinical significance of platelet dysfunction demonstrated in vitro is unclear. Although prolonged BTs are present in up to 40% of patients with cirrhosis and appear to be correlated with disease severity, they have not been predictive of bleeding.[13] Improvement in BT in randomized trials of DDAVP (desmopressin) did not translate into reductions in surgical blood loss, transfusion requirements, or improved control of variceal hemorrhage.[14,15] This discordance between laboratory findings and clinical bleeding may be explained by two observations. First, platelets studied under physiologic flow conditions show normal adhesion to fibrinogen and collagen even in cirrhosis.[16] Second, elevated levels of von Willebrand Factor (vWF) are commonly found in patients with cirrhosis and may compensate for thrombocytopenia or platelet dysfunction.

Platelet transfusions can be used to treat thrombocytopenia caused by liver disease but are generally not indicated unless the patient has severe thrombocytopenia less than 10 to 20 $\times$ 10^9/L or platelets less than 50 $\times$ 10^9/L with bleeding symptoms.[17] Platelet counts greater than 50 to 70 $\times$ 10^9/L are usually considered adequate for invasive procedures.[17] Less commonly attempted interventions for thrombocytopenia secondary to liver disease include splenectomy, partial splenic arterial embolization, and transjugular intrahepatic portosystemic shunt (TIPS), which are associated with unpredictable results and procedural risks. Thrombopoietin mimetic agents (e.g., eltrombopag, romiplostim) may offer potential treatment for these patients. In a phase II trial of 74 patients with hepatitis C–related cirrhosis and platelet counts of 20 to 70 $\times$ 10^9/L randomized to eltrombopag (30, 50, or 75 mg/day) or placebo, the primary endpoint of achieving a platelet count greater than 100 $\times$ 10^9/L at week 4 was seen in 75% to 95% of patients taking eltrombopag compared with 0% in the placebo group. Furthermore, 36% to 65% of patients taking eltrombopag were able to complete a 12-week course of antiviral treatment compared with 6% of the placebo group.[18] However, another trial evaluating eltrombopag in chronic liver disease was stopped because of an increase in portal vein thrombosis, highlighting some of the toxicities that can be associated with these new agents. Further study is required before recommendations can be made about their use.

COAGULATION AND LIVER DISEASE

The manifestations of aberrant coagulation in liver disease reflect a complex interplay between procoagulant and anticoagulant mechanisms. Patients with cirrhosis are recognized not only to be at increased risk of bleeding but also thrombosis.

Deficiencies in coagulation factors, vitamin K deficiency, dysfibrinogenemia, and systemic fibrinolysis can all contribute to impaired hemostasis.[19] Clinical manifestations can range from asymptomatic laboratory abnormalities to life-threatening hemorrhage.

Cirrhosis is marked by reduced synthesis of most coagulation factors. The number and degree of clotting factor deficiencies reflect the severity of liver damage. With the shortest half-life of approximately 6 hours, factor VII levels often decline early and are reflected by prolongation of the prothrombin time (PT). Factor VIII levels may be normal or elevated because of extrahepatic synthesis, increased

vWF levels, or impaired hepatic clearance. Being an acute phase reactant, fibrinogen synthesis is generally preserved unless liver disease is severe.

Reductions in factors II, VII, IX, and X may also result from vitamin K deficiency. For these coagulation factors, vitamin K is required as a cofactor in γ-carboxylation, a process that converts inactive precursors to biologically active factors. Vitamin K deficiency associated with liver disease can occur as a consequence of malnutrition, malabsorption, use of antibiotics, or biliary tract obstruction.

Defects in coagulation factors are suggested by prolonged PT and partial thromboplastin time (PTT) measurements and confirmed by individual factor levels. PT can also be expressed as the international normalized ratio (INR), a measure developed and validated to standardize PT measurements across laboratories for monitoring of vitamin K antagonist (VKA) therapy. Both the PT and INR have been incorporated into prognostic indices (Child-Pugh and model of end-stage liver disease [MELD]) to estimate the severity of liver disease and stratify patients for transplant, respectively. Furthermore, these parameters have been applied to estimate bleeding risk and guide therapy. Several significant limitations exist in applying these laboratory parameters in the context of liver disease. First, PT, PTT, and INR have been shown to correlate poorly with gastrointestinal or procedural bleeding.[20,21] Second, the INR has not been validated for patents with cirrhosis. Wide variations in INR have been observed in cirrhosis and may therefore undermine the utility and objectivity of the MELD index. Third, because these parameters suboptimally predict bleeding, the value of correcting these abnormal values with plasma or procoagulant agents becomes uncertain. Several reasons may account for the lack of correlation between PT or PTT with bleeding. Liver disease results in deficiencies of procoagulant proteins but also deficiencies in the natural anticoagulant proteins, including antithrombin and proteins C and S. PT and PTT assays are designed to be sensitive to procoagulant protein levels and do not reflect these alterations in anticoagulant proteins. Small studies have demonstrated normal thrombin generation and potential resistance to thrombomodulin in cirrhotic patients. Furthermore, factor VIII levels are increased in cirrhosis.[22]

Acquired dysfibrinogenemia has been described in approximately 75% of patients with chronic liver disease, acute liver failure, and cirrhosis. Aberrant polymerization of fibrin monomers may be related to excess sialic acid residues on fibrinogen, interfering with the activity of thrombin.[23] Laboratory findings in dysfibrinogenemia include elevated PT, PTT, or thrombin time; low or normal fibrinogen by immunologic assay; and reduced fibrinogen by functional assay. Despite these objective abnormalities, dysfibrinogenemia is not thought to contribute significantly to bleeding in most patients with liver disease.

The presence of hyperfibrinolysis in liver disease and its contribution to bleeding risk is controversial. Triggers of increased fibrinolysis may involve release of tissue plasminogen activator (tPA) in the setting of infection or surgery, reabsorption of ascitic fluid with fibrinolytic activity, and altered synthetic or metabolic functions of the liver.[24] With the exception of tPA and plasminogen activator inhibitor-1 (PAI-1), all fibrinolytic and antifibrinolytic proteins are synthesized in the liver. Paradoxically, low levels of plasminogen, plasmin inhibitor, factor XIII, and thrombin activatable fibrinolysis inhibitor (TAFI) and high levels of tPA and PAI-1 have been reported in cirrhosis. Decreased hepatic clearance of tPA and reduced synthesis of α2 anti-plasmin and TAFI favor an increase in circulating plasmin and a hyperfibrinolytic state in cirrhosis. Available laboratory tests measure individual components but cannot adequately assess the overall activity of profibrinolytic and antifibrinolytic components. Shortened whole blood euglobulin clot lysis time and elevated levels of D-dimer, fibrin, and fibrinogen degradation products are suggestive of increased fibrinolysis. These abnormal laboratory indices have been observed in nonbleeding patients but are seen more frequently in bleeding patients and have been reported to correlate with gastrointestinal bleeding, severity of liver failure, and variceal size. Hyperfibrinolysis may theoretically aggravate bleeding through secondary effects on other aspects of hemostasis, such as consumption of coagulation factors, inhibition of fibrin polymerization, and reduced platelet aggregation via degradation of vWF and glycoprotein Ib and $\alpha_{IIb}\beta_3$. Hyperfibrinolysis likely plays a more important role in hemostasis in the context of liver transplantation.[24]

TREATMENT OF LIVER DISEASE–RELATED BLEEDING

Because there is minimal correlation between laboratory abnormalities and bleeding, treatment and correction of asymptomatic hemostatic abnormalities is generally not indicated. Intervention is indicated when there is active bleeding or a planned invasive procedure or surgery.

Red blood cell transfusions should be provided to maintain an adequate hemoglobin or hematocrit and for symptomatic anemia. Generally, platelet transfusions are not indicated for isolated thrombocytopenia in the absence of bleeding. An effort should be made to maintain platelet counts greater than 50 to 70 $\times 10^9$/L with active bleeding or before invasive procedures.[17] Platelet transfusion may be effective if there is suspected platelet dysfunction. Patients with cirrhosis often have smaller platelet increments in response to transfusions caused by splenic sequestration.

A trial of oral vitamin K can be considered in patients with prolonged PT or INR. Vitamin K can be given intravenously for earlier onset of action but carries the small risk of anaphylaxis. Subcutaneous and intramuscular administrations are not preferred because of inconsistent absorption and risk of hematoma formation, respectively. If no improvement is seen after 10 to 20 mg of vitamin K, additional

*Differentiating between vitamin K deficiency and liver disease can be challenging with conventional laboratory tests. If available, performing a factor II assay with and without Echis venom (factor II biological and factor II Echis) may be useful. Ecarin is derived from Echis carinatus snake venom and can activate prothrombin irrespective of γ-carboxylation. Factor II activity (biological) is reduced in both vitamin K deficiency and liver disease. In contrast, the factor II Echis is reduced in liver disease but is normal in vitamin K deficiency.

vitamin K is unlikely to be beneficial. Although it may be reasonable to use vitamin K replacement alone in asymptomatic patients, it should be considered as an adjunct to other therapy in actively bleeding patients.

Fresh-frozen plasma (FFP) has traditionally been used to correct liver-related coagulopathy because it replaces all the coagulation and fibrinolytic factors. Despite its widespread use, its clinical effectiveness in reducing bleeding has not been supported by data from randomized controlled trials.[25] Guidelines variably support the use of 10 to 20 mL/kg of FFP for major hemorrhage, prevention of bleeding before major invasive procedures, or prevention of bleeding in acute liver failure.[17,26,27] Laboratory parameters, including a complete blood count (CBC), PT, PTT, fibrinogen, and D-dimer, should be followed to assess therapeutic effect. Generally, moderate correction of the PT and PTT is achieved after FFP transfusion but is transient, and repeat doses may have to be administered every 6 to 12 hours to maintain the effect. Patients should be monitored for complications of FFP, including transfusion reactions, risk of bloodborne infections, transfusion-related lung injury, and volume overload.[26] It may not be well tolerated in patients with liver disease who already have expanded intravascular plasma volume. Plasma exchange in addition to FFP has been described primarily in the setting of acute liver failure and in preparation for liver transplantation. However, the efficacy of this approach has not been thoroughly studied in controlled trials.

The presence of hyperfibrinolysis, DIC, and dysfibrinogenemia may exacerbate bleeding and are inadequately treated with FFP alone. These disorders should be suspected if coagulation parameters fail to correct with FFP or there is persistent bleeding. Administration of cryoprecipitate, rich in fibrinogen, vWF, factor VIII, and factor XIII, may help control bleeding. One unit of cryoprecipitate for every 10 kg of body weight increases plasma fibrinogen by approximately 50 mg/dL. Cryoprecipitate carries similar risks to FFP. Although antifibrinolytic agents could be considered in the setting of hyperfibrinolysis, no randomized trials have demonstrated efficacy or safety outside the setting of liver transplantation. Aprotinin and tranexamic acid have been shown to reduce blood loss and the need for transfusion in liver resection and transplantation.[28] Because of concerns regarding an increased risk of renal failure, stroke, heart failure, and death, aprotinin has been withdrawn from the market. Furthermore, thrombotic risks must be weighed and DIC must be excluded before usage.

Three- and four-factor prothrombin complex concentrates (PCCs) contain the vitamin K–dependent factors II, IX, and X and may or may not contain variable amounts of factor VII. They have proven to be effective in reversing anticoagulation with VKAs, but they have not been widely studied in liver disease. Data are limited to case reports and small, uncontrolled studies describing improvement in coagulation parameters, subjective clinical improvement, and safe administration in patients with liver disease.[29,30] Still, the use of PCCs in liver disease should be undertaken cautiously because of the risk of DIC, thrombotic complications, and anaphylaxis; its use should be restricted to emergency situations such as refractory bleeding or if FFP administration is limited by risk of circulatory overload.[31]

Recombinant FVIIa (rFVIIa) is formally approved for the treatment and prevention of bleeding episodes in patients with hemophilia and inhibitors, acquired hemophilia, and congenital factor VII deficiency. Because of proven efficacy in these other disorders, rFVIIa has been investigated for gastrointestinal or variceal bleeding in liver disease, liver resection or biopsy, and liver transplantation.[32-34] Studies have demonstrated transient normalization of the PT after rFVIIa, yet correlation with improved clinical outcomes has been inconsistent.[34,35] The only two randomized trials examining rFVIIa in active gastrointestinal and variceal bleeding did not show any benefit over placebo.[32] rFVIIa appears to reduce blood loss and blood product requirements when used prophylactically in invasive procedures or surgery; however, there is no clear mortality benefit.[36] These potential benefits may be offset by an observed increase in arterial thromboembolic events, particularly in elderly adults.[37] Compared with FFP, rFVIIa can be given in small volumes and has no infectious risk. Additional research is required to establish the overall benefit and risk of rFVIIa, and clinicians should proceed with the use of rFVIIa judiciously in the interim.

Management of Coagulopathy in Liver Disease

- Actively bleeding patients should be adequately resuscitated and stabilized with crystalloid or colloid solutions (or both). Admission to the intensive care setting may be appropriate.
- Basic coagulation tests should be ordered to identify the cause of bleeding; these include CBC, PT (INR), PTT, thrombin clotting time, fibrinogen, D-Dimer, FDP, and mixing studies. The need for more specialized tests will be dictated by the clinical situation and response to therapy.
- It is important to identify any localized source of bleeding (e.g., varices) amenable to procedural intervention because this will assist in achieving hemostasis.
- A trial of 5 to 10 mg of vitamin K is reasonable in asymptomatic patients with prolonged PT and PTT but should be used with other therapies in actively bleeding patients.
- Platelet transfusions can be used, targeting counts greater than 50×10^9/L.
- In patients who can tolerate volume, FFP 4 to 6 units (1000-1500 mL) given over 1 to 2 hours can be used to replace coagulation factors. Coagulation parameters should be monitored to document effect and determine the timing and need for additional units.
- Dysfibrinogenemia or hypofibrinogenemia should be suspected if coagulation assays do not correct with FFP or fibrinogen levels are low, respectively. Replacement can be attempted with 10 to 20 units of cryoprecipitate while following laboratory results.
- Patients who are intravascularly overloaded or who do not respond to FFP should be considered for rFVIIa. Low doses of rFVIIa (25-50 μg/kg) are generally used, and repeated doses may be required because of the short half-life of 2 to 3 hours. rFVIIa may thus be most suitable as a temporizing measure to enable invasive procedures or hemostasis to be achieved by other means. Avoid use in the setting of DIC.

HYPERCOAGULABILITY AND THROMBOSIS IN PATIENTS WITH LIVER DISEASE

Although retrospective studies have reported variable rates of venous thromboembolism (VTE) in patients with cirrhosis, it is clear that these patients are not immune to thrombotic events as once believed. Reported incidences of deep venous thrombosis (DVT) or pulmonary embolism (PE) have ranged from 0.5% to 6.3%.[38] Thrombotic complications can also involve portal, mesenteric, and hepatic veins. Portal vein thrombosis (PVT) occurs in approximately 8 to 15% of patients with cirrhosis and is associated with both severity of disease and inferior prognosis in liver transplantation.

The frequency of thrombotic events in patients with liver disease indicates that some patients may benefit from prophylactic or therapeutic anticoagulation. Hepatic or portal vein thrombosis may result in worsening liver function, ascites, varices, and hemorrhage. Furthermore, microvascular thrombosis has been proposed to promote hepatic fibrosis and progression of cirrhosis.[39] Clinical decisions are limited by a paucity of studies establishing the optimal dose, duration, monitoring, or choice of anticoagulant and, more importantly, clear clinical benefit and safety.

With respect to prophylactic anticoagulation, there are currently no standard means of identifying high-risk patients and reconciling the perceived increased risk of bleeding in these patients. Guidelines

Hemostatic Balance in Liver Disease

	Promotes Thrombosis	*Promotes Bleeding*
Primary hemostasis	• Increased vWF • Decreased ADAMTS13	• Thrombocytopenia • Platelet dysfunction
Secondary hemostasis	• Increased factor VIII • Decreased protein C, protein S, antithrombin	• Factor deficiencies: II, V, VII, IX, XI • Vitamin K deficiency • Hypofibrinogenemia • Dysfibrinogenemia
Fibrinolysis	• Reduced plasminogen • Increased PAI-1	• Reduced α2-antiplasmin, TAFI, factor XIII • Increased tPA

on antithrombotic prophylaxis do not specifically address cirrhosis, so decisions to proceed with prophylactic anticoagulation remain individualized. Patients who may particularly benefit from primary prophylaxis are those awaiting liver transplantation because portal vein thrombosis worsens the long-term posttransplant prognosis. Small trials have recently suggested that low-molecular-weight heparins may be safe for thromboprophylaxis in cirrhosis.[38] Use of VKAs for thromboprophylaxis in patients with liver disease may be complicated by unreliable INR measurements. Trials involving newer anticoagulants such as direct thrombin and factor Xa inhibitors have usually excluded patients with liver disease.

A similar risk–benefit analysis must be completed before therapeutic anticoagulation for confirmed thrombosis. Expert opinion recommends screening for varices and appropriate treatment with β-blockers or endoscopic therapy before anticoagulant initiation to mitigate bleeding potential.[40] There are several indications for therapeutic anticoagulation in the setting of cirrhosis, including DVT or PE, acute PVT, and Budd-Chiari syndrome. The comprehensive management of these disorders is beyond the scope of this chapter. Treatment options for portal vein or hepatic vein thromboses may include one or more of anticoagulation, systemic or local thrombolysis, or TIPS. The American Association for the Study of Liver Diseases' 2009 guidelines recommended a minimum of 3 months of anticoagulation for acute PVT in the absence of cirrhosis, with consideration for long-term anticoagulation in patients with persistent thrombotic risk factors or concerns for extension into mesenteric veins.[40] Individualized assessment has been recommended for patients with PVT with cirrhosis.[40] Overall recanalization after 6 months has been observed in up to 75% of PVT patients with cirrhosis and minimal major bleeding.[41] The value of anticoagulation for chronic PVT is uncertain, particularly in patients with cirrhosis with varices. Hepatic vein thrombosis is more uncommon than PVT, and even less evidence exists to guide therapy. Anticoagulation is usually instituted acutely and maintained long term to prevent recurrence in the absence of contraindications. Symptomatic patients may go on to have additional interventional therapies as mentioned above, as well as possible liver transplantation.[40]

FUTURE DIRECTIONS

Liver disease can cause a variety of hematologic manifestations. Patients may have concurrent coagulopathic, hypercoagulable, and hyperfibrinolytic features. Bleeding or thrombosis may be the end result of a reduced capacity of the hemostatic system to maintain homeostasis in the face of physiologic stress. Advancements in patient care will evolve with improved understanding of pathophysiology and refinement of laboratory assays.

CHAPTER 156

HEMATOLOGIC MANIFESTATIONS OF SYSTEMIC DISEASE: RENAL DISEASE

Peter W. Marks, Rachel Rosovsky, and Edward J. Benz, Jr.

Disorders of the kidney can be associated with very significant hematologic effects. Significant compromises of renal function have major adverse effects on red blood cell production and platelet function but can also affect red cell morphology and survival, leukocyte function, and coagulation factors. Understanding the pathogenesis of these changes facilitates accurate diagnosis and management of hematologic abnormalities encountered in patients with renal disease.

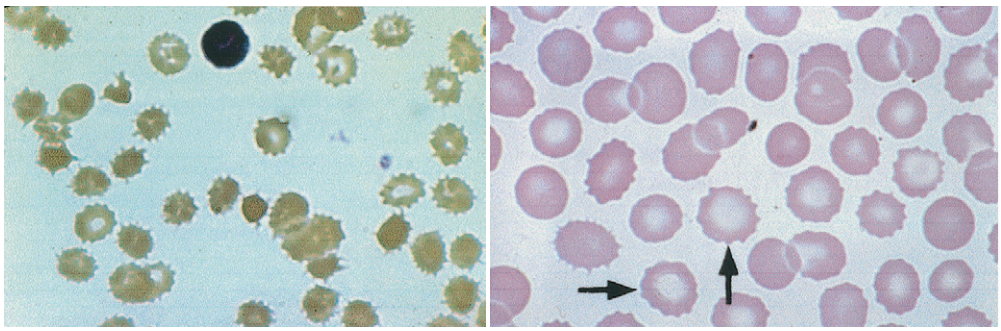
Because the kidney is the locus for the production of erythropoietin, the primary driver of red blood cell production, it is hardly surprising that renal injury is almost always accompanied by anemia. Indeed anemia is usually the most prominent hematologic manifestation encountered in patients with renal dysfunction. It is widely appreciated that end-stage renal disease is associated with severe anemia (see later). However, even modest renal damage, such as that seen in diabetic patients with very modestly elevated serum creatinine levels, can be associated with impaired erythropoietin production.

Renal disease can also lead to defects in red blood cells, platelets, leukocytes, and coagulation factors. In addition, acquired disorders arising outside of the kidney, such as hemolytic uremic syndrome (HUS), can manifest simultaneously as hematologic and renal disturbances.

Abnormal red blood cell morphology due to uremia is usually manifested by the presence of echinocytes (burr cells) on the peripheral blood smear (Fig. 156-1). The pathogenesis underlying this morphologic change remains unknown despite many efforts to provoke the abnormal erythrocyte topology with substances accumulating in renal failure plasma. Uremic toxins are likely the culprit responsible for significant impairments in platelet function that are often encountered in these patients. The abnormality closely resembles an acquired aspirin-like platelet release defect. This finding, in combination with a decreased quantity and/or function of certain clotting proteins, including von Willebrand factor, can lead to significant bleeding complications. Cellular and humoral immunity mediated via lymphocytes are also adversely affected in renal disease,[1] and a wide variety of leukocyte defects have been reported in this setting.[2] In clinical practice, however, hypoproliferative anemia, bleeding complications, and HUS are the most frequent clinically relevant entities encountered, so they are covered in greater detail here.

MANAGEMENT OF HYPOPROLIFERATIVE ANEMIA

End-stage renal disease is a major health problem in the United States, with incidence increasing every year. The associated anemia is thus a cause of significant morbidity and mortality on a public health scale. Although the cause of the anemia is multifactorial, reduced erythropoietin production is primarily responsible. Erythropoietin is a glycoprotein hormone synthesized primarily in the kidney.[3,4] This crucial component in the regulation of hematopoiesis is essential for the proliferation, maturation, and differentiation of erythroid precursors (see Chapter 24).[5]



Previously the great majority of patients on dialysis required chronic blood transfusions. This situation has changed dramatically with the introduction of recombinant human erythropoietin (rHuEPO) into clinical practice (see box on Management of the Anemia of Renal Disease). In addition to accelerating erythropoiesis and reducing allogeneic blood transfusions, rHuEPO has been shown to increase exercise capacity and improve quality of life, sleep, cognitive function, and sexual function in anemic patients with chronic renal failure.[6-10] A small number of prospective and retrospective clinical studies has also shown that treatment with rHuEPO decreases the rise in creatinine, slows the decline of glomerular filtration rate, and delays initiation of dialysis in patients with chronic renal failure. The results from these few exploratory clinical trials support the hypothesis that using rHuEPO and correcting anemia may slow the rate of progression of renal failure.[11-13]

Treatment of anemia may also have significant cardiovascular benefits in this population. A few recent studies have shown that left ventricular hypertrophy is directly related to the level of anemia in chronic renal failure patients.[8-10] In addition, left ventricular mass has been shown to be an independent determinant in the survival of patients on dialysis.[14] Thus treatment with rHuEPO may have benefits in terms of cardiac function and subsequently survival for these patients.[15] However, data also suggest that excessive correction of the hemoglobin level to values greater than approximately 12 g/dL is associated with an increased incidence of cardiovascular and thromboembolic events. There are also theoretical concerns, supported by animal and cell culture data, that erythropoietin might stimulate the proliferation of some neoplastic cells. Therefore the use of erythropoiesis-stimulating agents to increase hemoglobin values to greater than 12 g/dL is not routinely recommended.

Although rHuEPO can be administered intravenously or subcutaneously, the subcutaneous route appears to be advantageous. It is easier to administer and can be given less frequently. Hypertension and, to a much lesser degree, thrombosis have been reported in patients on dialysis.[13,16] In addition, a short-lived influenza-like syndrome has been described.[17] Rare side effects include allergic reactions, seizures, hyperkalemia, and thrombocytosis. Pure red blood cell aplasia, thought to be due to the development of antierythropoietin antibodies, is also a rare but serious complication that has primarily been reported with certain preparations of rHuEPO.[14,15,18]

An increase in the hemoglobin level to greater than 10 g/dL after a 4-week course of therapy is frequently the target goal when administering rHuEPO. Some patients may fail to respond or may be resistant to the effects of rHuEPO. The most common cause for a failure in response is iron deficiency anemia.[19] Other contributing factors that may affect the response are cobalamin or folate deficiency, infection, chronic inflammation, secondary hyperparathyroidism, malnutrition, hemoglobinopathies, aluminum toxicity, or bone marrow fibrosis.[17,20-22]

Iron deficiency is almost universal in the dialyzed patient. Gastrointestinal bleeding, blood draws, and hemodialysis all contribute to this iron-deficient state.[23] In addition, by accelerating erythropoiesis, rHuEPO actually can cause functional iron deficiency.[19,20] As a result, iron supplementation in chronic renal failure patients is usually essential. Even with the most rigorous protocols, oral iron preparations have not been as effective as intravenous ones, largely because of poor absorption resulting in failure to maintain adequate hematologic parameters (hemoglobin level >11 to 12 g/dL, transferrin saturation >20%, plasma ferritin concentration >100 ng/mL). Thus intravenous iron is often administered.[24,25] There are now multiple formulations of intravenous iron available for administration, including iron

A B

Figure 156-1 MORPHOLOGY OF ACANTHOCYTES AND ECHINOCYTES. **A,** Acanthocytes, or spur cells, are most commonly observed in significant numbers on the peripheral blood smear in cases of liver disease, although they may also be prominent in certain rare disorders (e.g., alpha, beta-lipoproteinemia). Their characteristic features are spines that seemingly project from the surface of the cell. Such morphologic change represents the result of irreversible cytoskeletal damage due to passage of abnormally stiff cells through the reticuloendothelial system. **B,** Echinocytes, or burr cells, are the hallmark of uremia, although they may be observed as an artifact on less than optimally prepared smears. An undulating or bumpy red blood cell surface *(arrows)* characterizes this morphologic change, the cause of which is unknown.

Management of the Anemia of Renal Disease

Recombinant human erythropoietin (rHuEPO) and the longer-acting modified erythropoietin, darbepoetin, have revolutionized treatment of the anemia of renal disease. However, owing to their potential for adverse events, the potential inconvenience of their administration by the parenteral route, and their expense, they should be used thoughtfully and judiciously.

Regardless of the extent of renal insufficiency, patients who are candidates for erythropoietin replacement should have an assessment of their iron stores. Analysis of serum parameters, such as ferritin, iron, and transferrin, generally suffice for this purpose. If there is any hint that iron deficiency may be present, it should be addressed before, or at least concomitantly with, the administration of rHuEPO. Although oral replacement may be reasonable in a patient with borderline iron stores and renal insufficiency, intravenous replacement with iron dextran, iron gluconate, or iron sucrose should be considered in patients with more severe iron deficiency or renal failure.

In the setting of mild to moderate renal insufficiency, such as that often seen in diabetic patients, it is not unreasonable to initiate therapy on a weekly basis if using rHuEPO or every other week when using darbepoetin when the hemoglobin level is less than 9 g/dL. After the hemoglobin concentration increases to greater than 10 g/dL, the frequency of administration or dose can be tapered to maintain a level between 10 and 11 g/dL. In some exceptional circumstances, such as in patients with significant congestive heart failure or pulmonary disease, maintenance of hemoglobin at a higher level (between 11-11.5 g/dL, but not above) may be determined to be beneficial. However, this should only be done with extreme caution, since the use of rHuEPO to raise levels above 11 g/dl has been associated with increase risk of cardiovascular events and death.

If there is no response to erythropoietin after 4 to 8 weeks of weekly therapy with rHuEPO or biweekly therapy with darbepoetin, iron stores should be reevaluated. If adequate, dose escalation of rHuEPO or darbepoetin by 50% and an additional trial for 4 to 8 weeks is reasonable. After that time, however, the drug should be discontinued and consideration be given to the cause for the lack of response, which is otherwise rare in the setting of anemia purely due to renal insufficiency. New formulations of rHuEPo are appearing; doing will vary by preparation. Dosing should be adjusted to maintain hemoglobin levels in the aforementioned target ranges.

dextran (InFeD), sodium ferric gluconate complex (Ferrlecit), and iron sucrose (Venofer). The latter two preparations are often used because they would appear to have more favorable safety profiles.[22,26-28] In particular, anaphylactic reactions appear to be somewhat less common.[29]

A hyperglycosylated rHuEPO, darbepoetin (Aranesp), is available.[30] It has the same mechanism of action as rHuEPO with the advantage of having a twofold to threefold longer half-life.[31,32] Consequently it can be dosed less frequently, allowing for fewer injections.[33,34] Darbepoetin appears to be equivalent to rHuEPO in terms of its clinical outcomes in patients with chronic renal failure, specifically in reaching a target hemoglobin level, the time it takes to reach that target, and the percentage of patients who reach that goal.[35,36] It is also a well-tolerated medication and has a safety profile that is similar to that of rHuEPO.[37,38] There have been no antibodies to native or recombinant erythropoietin detected to date in patients treated with darbepoetin.

HEMOSTATIC AGENTS FOR USE IN UREMIA

Bleeding from uremia is one of the major causes of morbidity in patients with end-stage renal disease.[32,33] There are multiple factors contributing to the pathogenesis of this bleeding risk, but recent focus has centered on platelet dysfunction,[35,36,39] abnormal platelet–vessel wall interactions,[37] retention of uremic toxins,[38] presence of anemia, and increased levels of nitrous oxide.[40-42]

The hemorrhagic manifestations commonly seen with uremia include epistaxis, gastrointestinal and genitourinary bleeding, subdural hematomas, hemorrhagic pericarditis, ecchymoses, and prolonged bleeding from skin puncture sites. A number of therapeutic options exist for the treatment of the hemorrhagic diathesis caused by uremia, and these should be considered in any patient who is actively bleeding or about to undergo a surgical procedure.

Correction of anemia with either red blood cell transfusions or recombinant human erythropoietin contributes significantly to reducing the bleeding tendency. Raising the hematocrit to 27% or greater has been shown to decrease the bleeding time and improve platelet function.[43-45] Similarly, hemodialysis has been shown to partially correct the bleeding time and potentially decrease the risk for bleeding.[46]

Perhaps the most convenient and safest treatment for bleeding in the setting of uremia, regardless of whether a patient is being dialyzed, is the use of desmopressin (DDAVP). Possibly through release of von Willebrand factor from endothelial stores and through improved

platelet signal transduction, it frequently improves hemostasis. In a randomized placebo-controlled trial, administration of 0.3 mcg/kg of DDAVP resulted in a decrease in the bleeding time 1 hour after the infusion. However, the duration of action was relatively short and the improvement lasted only 6 to 12 hours.[47] If a longer duration of action is needed, administration of conjugated estrogens can be considered.[42,48] An intravenous dose of 0.6 mg/kg is given daily for 5 days. Although estrogens are slower in their onset of action, and perhaps somewhat less reproducible in terms of response, their effect can last 7 to 10 days. The mechanism of action of estrogens is not well understood but may be related to their effects on nitrous oxide. Finally, cryoprecipitate, rich in von Willebrand factor and fibrinogen, can also sometimes temporarily correct the bleeding time. It appears to act as quickly and last as long as DDAVP. A commonly used dose is 10 units every 12 to 24 hours.[49]

MANAGEMENT OF HEMOLYTIC UREMIC SYNDROME AND THROMBOTIC THROMBOCYTOPENIC PURPURA

Hematologic and renal abnormalities can manifest nearly simultaneously and suddenly in two disorders: HUS and thrombotic thrombocytopenic purpura (TTP)(see Chapter 136). Distinguishing between these two entities can be difficult.[50,51] They are both characterized by thrombocytopenia, microangiopathic hemolytic anemia, and platelet aggregation ultimately leading to end-organ dysfunction.[52] In HUS, the microvascular thrombi tend to occur within the renal microcirculation, causing acute renal failure. In TTP, the microvascular ischemia occurs in many organs and may affect the cerebral circulation, causing neurologic abnormalities.

Although not infrequently idiopathic, both HUS and TTP have been associated with the administration of various medications such as cyclosporine (HUS) and clopidogrel (TTP). In addition, the occurrence of HUS has been associated with Shiga toxin–producing bacteria (*Escherichia coli* 0157:H7).[47] Interestingly, the clinical course of HUS appears to depend on cause. Children who suffer from postdiarrheal HUS generally improve on their own with supportive care, and they only occasionally require short-term dialysis.[53] Patients with medication-related HUS tend to have poorer prognoses.

Deficiencies in factors of the alternative complement pathway have been associated with HUS, and ADAMTS13 deficiency has been found in some patients with TTP.[49,54,55] However, rapid determination of the level of these proteins is not yet routinely available, so the distinction between HUS and TTP, when made, generally relies on associated clinical findings.

In adults, HUS and TTP are often managed similarly by clinicians. Plasma-based therapies have been demonstrated to significantly decrease the mortality rates associated with HUS-TTP, and studies have documented the value of plasma exchange over simple plasma infusion.[56,57] The efficacy of plasma exchange possibly comes from its ability to remove the toxic factors implicated in the initiation of these disorders as well as to replace a depleted, missing, or inhibited factor such as the ADAMTS13 protease.[58,59] Some clinicians advocate that plasma exchange should begin promptly in any individual suspected of having HUS or TTP, regardless of whether the former or the latter is more strongly suspected.[60] Daily therapy with total plasma exchange is recommended until remission is evident, as determined by resolution of any renal and/or neurologic failure, normalization of platelet count and lactate dehydrogenase level, and a stable hematocrit level reflecting absence of ongoing hemolysis, or until it is clear that no further clinical benefit is being derived. Further research will hopefully better elucidate the pathogenesis of HUS and TTP and thereby facilitate the development of tailored therapies for each of these entities.

FUTURE DIRECTIONS

There are numerous hematologic manifestations of renal disease ranging from morphologic changes of red blood cells to coagulation abnormalities affecting hemostasis. Optimal patient care is facilitated by an understanding of these associated complications and their appropriate management.

CHAPTER 157

HEMATOLOGIC MANIFESTATIONS OF CANCER

Gerald A. Soff, David L. Green, and Lawrence B. Gardner

Hematologic abnormalities are often seen in a variety of nonhematologic cancers. These manifestations range from trivial to life-threatening and may complicate management and require additional therapy. Some of these abnormalities can be the initial manifestation of cancer, providing a crucial diagnostic clue (e.g., Trousseau syndrome or erythrocytosis). Finally, the hematologic aspects of cancer can provide insight into the biology of tumorigenesis. This chapter focuses on the role of nonhematologic malignancies on red cells, platelets, and coagulation. Abnormalities seen with hematologic malignancies (e.g., the hemolytic anemia noted with chronic lymphocytic leukemia, or microangiopathic hemolytic anemias during bone marrow transplant) are addressed within those specific chapters.

CYTOPENIAS AND CANCER

Anemia

The most common hematologic manifestation of cancer is anemia, with studies demonstrating 30% to 90% of patients with cancer having anemia before treatment, including 40% of patients with early-stage colon cancer and 80% of patients with advanced colon cancer.[1] The causes of this anemia are varied. In gastrointestinal cancers, or cancers metastatic to the gastrointestinal tract, as well as in bladder cancer, iron deficiency from bleeding is common. More rarely, tumors involving the small bowel can interfere with iron absorption and/or vitamin B_{12} absorption. Most cancers are associated with systemic inflammation, manifested by elevated levels of cytokines, which can directly inhibit erythropoiesis and suppress iron available for erythropoiesis, both features of the anemia of chronic inflammation (see Chapter 35). Specifically, serum erythropoietin concentrations are not as elevated in patients with cancer as they are in patients with the same degree of anemia due to iron deficiency, and cancer patients often demonstrate increased hepcidin levels. Hepcidin decreases the iron transporter ferroportin, which results in increased iron stores (in the form of ferritin) and a decrease of free iron available for erythropoiesis, classic serologic findings in patients with cancer and anemia.

Another common cause of anemia in patients with cancer is bone marrow suppression due to chemotherapy. The European Cancer Anaemia Survey prospectively studied over 15,000 patients with a variety of solid tumors and treatments for 6 months.[2] Before therapy 10% of patients had hemoglobin levels below 10 g/dL, and during therapy this increased to almost 40% and correlated with poor performance status. In this study, radiation therapy alone did not dramatically increase the prevalence of anemia, but the combination of chemotherapy and radiation led to a greater degree of anemia than chemotherapy alone. Anemia due to chemotherapy is related to cumulative dose (e.g., there is a significant correlation of anemia with total cisplatinum dose), drug combinations (there is more anemia when cisplatinum is added to paclitaxel), and drug schedule (e.g., there is more anemia when paclitaxel is given over 24 hours compared to shorter time courses).[3] In contrast to iron deficiency and the anemia of chronic disease, anemia due to chemotherapy is generally associated with a similar or even greater decrease in platelets and neutrophils (due to their shorter half-lives), and it is important to note that specific chemotherapeutic agents are associated with particular cytopenias (e.g., gemcitabine and thrombocytopenia).[3] Although anemia in cancer patients plays an important clinical role because the degree of anemia correlates with quality of life, anemia can be treated with red cell transfusions and erythropoietin (see Treatment of Cytopenias Due to Cancer), whereas myelosuppression resulting in neutropenia and/or thrombocytopenia can be more difficult to treat and may result in significant morbidity and/or delay in treatment.

Thrombocytopenia

Although chemotherapeutic and immunosuppressive agents typically cause thrombocytopenia by suppressing hematopoiesis, they can also cause immune thrombocytopenia, and this diagnosis should be considered particularly when there is a sudden drop in platelets alone. For example, trastuzumab and oxaliplatin have both been shown to cause immune thrombocytopenia. Thrombocytopenia *independent* of treatment effect may be seen as a result of bone marrow infiltration by tumor cells, thrombotic microangiopathy, consumption coagulopathy, or rarely as an associated autoimmune manifestation. Bone marrow involvement, often occult, is common in prostate, lung, and breast cancer, although thrombocytopenia is not usually the sole presenting cytopenia. The laboratory features of disseminated intravascular coagulation (DIC) (elevated D-dimer and fibrinogen degradation products) are commonly seen in cancer patients (up to 90% of advanced cancers[4]), and DIC is the most common cause of non–treatment-related thrombocytopenia, although it is a relatively uncommon cause of bleeding in the cancer patient (see later).

Although thrombocytopenia often has a clinical impact because of bleeding or delays in the administration of chemotherapy, reactive thrombocytosis is actually more common than thrombocytopenia in cancer patients. Although in general thrombocytosis has not been associated with either bleeding or thrombotic events, prechemotherapy platelet count greater than 350,000 was a risk factor for venous thromboembolism (VTE) in a large prospective observational study of cancer patients undergoing chemotherapy.[5] Cancer-related thrombocytosis is likely to be a cytokine-mediated effect, and elevated levels of cytokines known to stimulate protein production, including interleukin-6 (IL-6), IL-11, and thrombopoietin (TPO), are often documented in cancer. In most tumor types, such as breast, renal cell, and gastric, elevated platelet counts confer an adverse prognosis.[6]

Multiple Cytopenias Due to Bone Marrow Metastases

When cancer is associated with the decrease of multiple lineages, the metastases of cancer to the bone marrow must be considered (Fig. 157-1). There are some data showing that platelet size can help differentiate thrombocytopenias due to bone marrow metastases from thrombocytopenia due to other causes, including immune thrombocytopenia, and decreased survival due to platelet activation and/or DIC seen in cancer.[7] Although all malignancies, even glioblastomas,

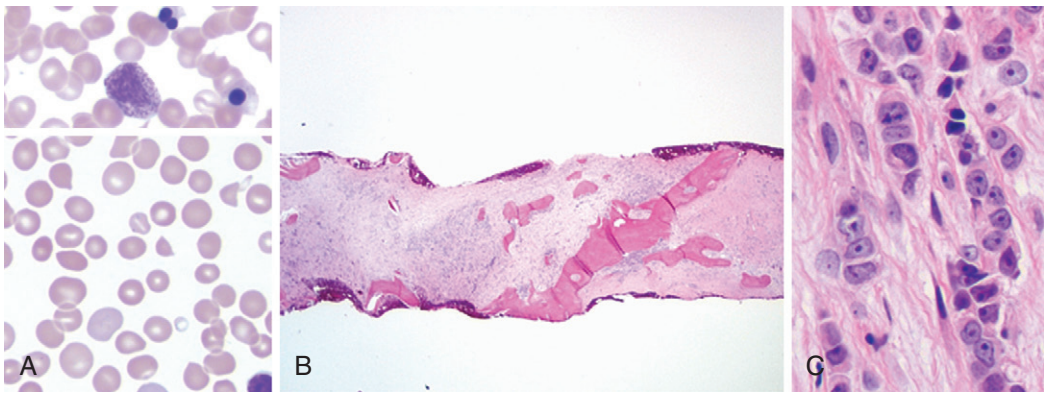

Figure 157-1 PERIPHERAL BLOOD AND BONE MARROW FROM A PATIENT WITH METASTATIC BREAST CANCER. THE PATIENT WAS A 77-YEAR-OLD WOMAN WHO PRESENTED WITH ANEMIA AND THROMBOCYTOPENIA. On physical examination she was found to have a breast mass. **A,** The peripheral smear showed a leukoerythroblastosis *(top)* with nucleated red blood cells and immature granulocytic precursors. Platelets were reduced, and red blood cells exhibited anisopoikilocytosis *(bottom)* with occasional teardrop forms and rare schistocytes. **B,** The bone marrow biopsy was fibrotic and had thickened bone with new bone formation. **C,** The bone marrow cavity was replaced by tumor cells infiltrating through bands of fibrosis.

have been reported to metastasize to the marrow, the most common malignancies include breast, gastric, lung, and prostate cancer. In one study, 8% of the time no primary tumor was identified at the time of bone marrow metastases, and only 13% of patients had normal blood counts at the time bone marrow involvement was noted.[8]

As expected, patients with bone marrow involvement of their solid tumor are more likely to experience cytopenias from chemotherapy, and bone marrow metastases carry a poor prognosis in virtually all solid malignancies.[8] For example, one study in patients with extensive small cell lung cancer found that those with bone marrow metastases had significantly shorter time to progression and significantly shorter survival time than other patients with extensive disease.[9] Although the poor prognosis in patients with bone marrow metastases is in large part due to tumor burden, the ability of a tumor to metastasize and grow in the bone marrow niche may indicate that the tumor has biologic features that render it particularly aggressive and/or resistant to therapy. Such tumor cell characteristics could include homing, adhesion, immune escape, and angiogenic potential. Laboratory data suggest that tumors that secrete more proangiogenic and proinflammatory cytokines may be more likely to metastasize to the bone marrow. Clinical data support the concept that the marked heterogeneity that exists within tumors includes characteristics that are required for growth with the bone marrow. One such example is the bone marrow micrometastases seen in women with early-stage breast cancer; 30.6% of women who have stage I to III breast cancer were found to have bone marrow micrometastases, and this was an independent poor prognosis in multivariable analysis.[10] Although bone marrow metastases also conferred a poor prognosis on women with small tumors and uninvolved lymph nodes, there was survival of patients even in the absence of chemotherapy, suggesting more factors may be necessary for cancer cells to grow in the bone marrow, and this may be an indicator of more aggressive disease rather than burden of disease. Indeed, a recent study of over 5000 women with T1N0M0 to T2N0M0 invasive breast carcinoma found that the presence of bone marrow metastases (found in 3% of patients) was an indicator of poor prognosis on univariate analysis, but not in multivariate analysis.[11]

The pathophysiology by which marrow involvement by cancer causes cytopenias is not fully understood. Total marrow replacement by tumor is rare, and only a small percentage of marrow can support normal peripheral blood counts, as indicated by the normal counts found in older adults with hypocellular marrows. Cancer may disrupt bone marrow niches required for normal hematopoiesis. Indeed, tumor growth in bone marrow may depend on specific niches that include osteoclasts as well as specific bone marrow stromal cell populations.

Other Cytopenias in Cancer

As noted, immune cytopenias, including immune thrombocytopenia, can occur as a complication of cancer treatment. Cancers can also cause autoimmune disorders resulting in cytopenias. Although this is commonly seen with thymomas and pure red cell aplasia, a variety of nonhematologic cancers can rarely lead to this phenomenon, including breast and lung cancer. Cytopenias can also be due to microangiopathic hemolytic anemias, leading to thrombocytopenia and anemia. Typically the white blood cell count is normal. Although a true incidence is difficult to determine, there are reports that 5% to 10% of mucin-producing disseminated adenocarcinomas result in a microangiopathic hemolytic anemia.[12] Although these microangiopathic syndromes are commonly referred to as thrombotic thrombocytopenic purpura (TTP), the pathophysiology appears distinct from idiopathic TTP, as suggested by the absence of very low levels of a disintegrin and metalloproteinase with thrombospondin motifs-13 (ADAMTS-13) and associated antibody inhibitors, and by the poor response to therapeutic plasma exchange. Some data suggest that cancer associated microangiopathy may result from endothelial damage. A microangiopathic hemolytic anemia may also be seen with the use of some drugs used in the treatment of cancer, including cyclosporine, mitomycin, and gemcitabine and anti–vascular endothelial growth factor (VEGF) agents.

EVALUATION OF CANCER-ASSOCIATED CYTOPENIAS

As in all cases of cytopenias, the initial step in the evaluation of cytopenias in a patient with cancer is a careful history and physical. Special emphasis should be placed on whether the patient suffers from an isolated cytopenia (e.g., anemia) or whether multiple lineages are affected, suggesting marrow suppression or involvement. Similarly, the temporal nature of the cytopenia, whether it correlates to therapy or is progressive, may suggest that it is therapy related or due to marrow involvement of cancer, respectively (see box on Evaluation of Cytopenias).

An examination of the peripheral blood smear is crucial. Appearance of a microangiopathy (fragmented red cells, thrombocytopenia, reticulocytosis) can suggest a TTP-like condition, DIC, or marrow replacement by tumor. In this case coagulation tests may be helpful, and a bone marrow aspirate and biopsy may be necessary. Finally, readily treatable causes of cytopenias that are common in the general population (e.g., iron deficiency) should be ruled out in all patients with cancer.

Evaluation of Cytopenias

The evaluation of cytopenias can be difficult, particularly in the complex patient who has cytopenia before receiving chemotherapy that is worsened with treatment. The anemia of inflammation and the anemia of iron deficiency, both of which are microcytic, can be difficult to differentiate, particularly because the serum ferritin level is an unreliable assessment of iron stores in inflammatory conditions such as cancer (as reviewed in Chapter 35). Marrow-occupying tumors are often associated with microangiopathic features, including schistocytes, teardrops, and bizarre red cell forms, leukoerythroblastosis, and thrombocytopenia. The peripheral smear and laboratory evaluation can be difficult to distinguish from primary bone marrow disorders and thrombotic thrombocytopenic purpura (TTP), and in some cases a bone marrow examination may be necessary, particularly if the involvement of marrow has prognostic or treatment implications.

TREATMENT OF CYTOPENIAS DUE TO CANCER

Cytopenias resulting from cancer and/or chemotherapy can be asymptomatic. However, anemia (particularly hemoglobin level below 8 to 10 g/dL) is thought to be a major contributor to fatigue and thus quality of life, leukopenia can lead to infections, and thrombocytopenia can either lead to spontaneous bleeding or make procedures, including intrathecal treatments, more dangerous. Cytopenias can also commonly cause delays in treatment or alterations in treatment.

The treatment of cytopenias is dependent on the underlying cause. For example, cytopenias due to marrow infiltration of a chemosensitive cancer are best treated with chemotherapy, although less-myelosuppressive regimens are most appropriate. In contrast, if the cytopenias are *due* to treatment, holding or delivering an alternative therapy is best. For cytopenias due to immune-mediated effects, steroids and other standard therapies are appropriate.

Because of the limitations and potential morbidities of transfusions, for almost two decades hematopoietic growth factors have been frequently used for therapy. Although erythropoietin and granulocyte colony-stimulating factor (G-CSF) have been most studied and used clinically, other growth factors (including platelet factors) have been developed. These therapies have primarily been studied in those receiving chemotherapy, although several studies using erythropoietin have included cancer patients not receiving chemotherapy, many of whom had an inflammatory anemia. Initial trials of erythropoietin treatment of thrice-weekly injections of erythropoietin, and later trials using weekly erythropoietin or longer-acting agents such as darbepoietin, have unequivocally demonstrated that the use of erythropoiesis-stimulating agents during myelosuppressive treatment increases hemoglobin level and decreases transfusion requirements by approximately 50%. Although many of these studies with these agents demonstrate an improvement of quality of life, most of these studies were not blinded, prospective, or definined a minimal quality-of-life metric that would be considered clinically relevant.

Despite the biologic effectiveness of erythropoietin in a variety of noncancer patients, several trials using erythropoietic growth factors led to no clinical improvement, or decreased improvement, in intensively ill patients, patients with heart failure, patients requiring hemodialysis, patients with severe renal dysfunction, and patients with a variety of other noncancer conditions (see Chapter 35). Similarly, a randomized trial showed that patients with cancer not receiving chemotherapy had increased cardiovascular and thromboembolic events and decreased survival over 4 months of treatment with darbopoietin, though the increased risks were not significant in multivariate analyses.[13] These studies and others had led to a consensus recommendation that erythropoiesis-stimulating agents not be used in those patients with cancer *not* receiving chemotherapy.[14]

Recently the prevalent use of erythroid, and even myeloid, growth factors in patients with cancer receiving chemotherapy has also been critically reassessed. Similar to what was seen in patients without cancer and in patients with cancer not receiving chemotherapy, the use of erythropoiesis-stimulating agents increases the rate of thrombosis (relative risk 1.67, compared to patients not receiving erythropoiesis-stimulating agents) during chemotherapy.[15] This risk for thrombosis correlates with the target hemoglobin. A large randomized trial in metastatic breast cancer patients of patients with mild anemia, targeting hemoglobin levels of 12 to 14 g/dL, demonstrated a decreased survival at 1 year, in part because of increased cardiovascular toxicity.[16] Similarly, patients receiving radiation for head and neck cancer, targeted to hemoglobin levels of over 14 g/dL, had a worse survival.[17] Metaanalyses have also demonstrated that thromboembolic events are increased in cancer patients receiving these agents[18-20] and have confirmed a relationship with target hemoglobin and risk for thromboses in cancer patients receiving erythropoietin.[21]

Of great concern is that both the breast cancer and head and neck studies cited earlier also demonstrated decreased tumor control with these, albeit high, doses of erythropoietin. Several randomized trials and metaanalyses, including one assessing almost 14,000 patients, have also found that the use of erythropoiesis-stimulating agents worsened overall survival, particularly in patients undergoing chemotherapy.[22] In other studies, although overall survival was not affected by concomitant erythropoietin use, local tumor control was decreased. However, it is important to note that this correlation has not been found in all analyses,[20,21] and in recent randomized trials of patients receiving radiation and chemotherapy erythropoietin did not alter survival (though hemoglobin was minimally increased).[23,24] A recent consensus stresses that reversible causes of anemia be ruled out before erythropoietin usage, that the minimal amount of erythropoietin be used to aim for a target hemoglobin level of 10 g/dL, and that erythropoietin only be used for patients receiving chemotherapy when palliation is the ultimate goal.[14]

The pathobiology of the increased rate of thromboses and the poorer rate of tumor control with erythropoiesis-stimulating agents is unknown. Although hemoglobin concentration correlates with thrombosis risk, suggesting that an increase in viscosity could be a causative factor, hemoglobin concentration could also serve as a surrogate for either effective erythropoietin dose or target cell (nonerythroid) responsiveness. In terms of the poor tumor control noted in some trials of erythropoietin, it has been noted that many tumor cells express erythropoietin receptors, and in fact increased erythropoietin receptor expression may be a poor prognostic indicator in many tumors. Erythropoietin signaling can serve as a survival signal, suggesting that targeting the erythropoietin receptor may be a therapeutic strategy in cancer therapy. Although it is reasonable to think that exogenous erythropoietin can promote tumor growth in this way, it is also possible that increased red cell mass and/or increased tumor oxygenation could play a role.

Myeloid growth factors (most commonly G-CSF) have also been used intensively in patients receiving chemotherapy over the past decade, with the goal of improving survival by intensifying the chemotherapy regimen, decreasing delays in chemotherapy administration, and decreasing infections and hospitalizations with neutropenic fever. G-CSF administration has also been suggested for regimens when the risk for neutropenia is greater than 20%. It is clear that many dose-intensive regimens, some of which may be more effective than less intensive regimens, are possible only with the support of myeloid growth factors. G-CSF receptors have been found on tumors, and there is a theoretic concern that exogenous G-CSF may increase proliferation and/or improve survival of these tumors. Use of myeloid growth factors during chemotherapy for solid tumors has been theorized to promote leukemia risk, by acting as a survival signal to hematopoietic progenitor cells damaged by chemotherapy. A recent metaanalysis of 25 randomized clinical trials found that there was an almost twofold increase in acute myeloid leukemia in those patients assigned to receive chemotherapy with growth factor support, compared to those who did not receive growth factor support, although all-cause mortality was actually decreased in those who received growth factor support.[25]

THROMBOSIS AND CANCER

Relationship of Cancer and Thrombosis

The association of thrombosis and cancer is widely recognized, dating to the middle of the 19th century, and can be considered the first recognized paraneoplastic syndrome. Armand Trousseau was the first to associate thrombosis and malignancy, the first to suggest screening for malignancy in recurrent or idiopathic thromboembolic disease, the first to suggest that the pathophysiology was not mechanical obstruction, but a change in the character in the coagulation system itself, and the first to suggest that the association may be integral to the cancer growth itself. What has made this association particularly poignant was the fact that Trousseau predicted his own occult malignancy when he developed "phlebitis," dying 6 months later of gastric cancer. More recently, some of the biologic mechanisms underlying the increased risk for thrombosis in patients with cancer have been better delineated (see later).

Patients with active malignancy have a higher risk for thrombosis than other medical patients, and surgical oncology patients have a higher thrombosis rate than other surgical patients undergoing major procedures. Although reports of thrombosis rates vary, it is generally accepted that about 15% to 20% of cancer patients will develop VTE at some point during their illness and about 20% of VTEs occur in cancer patients.[26] Cancer is a potent situational risk factor for venous thrombosis, increasing the risk about 6- to 10-fold. In comparison, the common hereditary thrombophilia, heterozygous factor V Leiden, increases the risk for venous thrombosis by approximately 5-fold (see Chapter 142). Arterial and venous thrombosis are second only to progression of disease as a cause of death among cancer patients, accounting for 9.2% of deaths among patients receiving outpatient chemotherapy.[27] There have been a number of reports characterizing the strength of the association of thrombosis with different cancer types, and these have yielded variable findings. The reported adjusted odds ratios for thrombosis for a given tumor type varies greatly, based on the methodology to capture the thrombosis diagnosis. But several important conclusions may be drawn. Virtually all solid tumor types, as well as hematologic malignancies, result in a significantly increased risk for thrombosis, and secondly, certain tumor types consistently appear to have particularly high risk for thrombosis, including lung, pancreas and other gastrointestinal cancers, and brain tumor.[28]

Not only does the diagnosis of thrombosis in the cancer patient require specific therapy that can complicate overall treatment strategies, it also serves as an important prognostic indicator. In patients with advanced cancer, those who present with venous thromboembolic disease have a 1-year survival of 12%, compared with 1-year survival of 36% in patients with advanced cancer presenting without thrombosis.[29] Similar studies have noted that the diagnosis of thrombosis during the first year after cancer diagnosis was a significant predictor of death for most cancer types and stages analyzed. One key question is whether the thrombotic tendency in some patients is mostly a marker of a more aggressive disease or the development of thrombosis is a major cause of increased mortality. Thrombosis is the second leading cause of death in outpatient chemotherapy patients, but of the 9.2% of total deaths attributable to thromboembolism, 3.5% were venous and 5.6% were arterial.[27] The preponderance of VTE events occur within the first 3 months of diagnosis, and not in the later stages of disease.[28] This can be interpreted as the thrombotic tendency is a property of the underlying cancer biology more than a reflection of tumor burden or a specific treatment strategy. And interestingly, in a recent study of gastroesophageal malignancy patients undergoing chemotherapy, multivariate analysis showed that development of a VTE during the course of chemotherapy was not associated with reduced survival.[30] These findings suggest that much of the mortality burden of venous thrombosis in cancer reflects the more severe underlying cancer biology rather than simply death from complications of the thrombosis itself.

Diagnosis of Coagulopathies in Cancer Patients

Thrombotic episodes in patients with cancer are typically diagnosed similarly to thrombotic events in patients without cancer. However, several subtleties exist. For example, thromboses may be confused with either intravascular disease progression and/or intravascular fungal infections. In many cases, the diagnosis of thromboses or an abnormality in coagulation may be made in an asymptomatic patient, leading to a difficult decision regarding the risks and benefits of correction. The constitutive activation of the coagulation system by cancer has been well documented. Elevated levels of markers of in vivo coagulation activation, including thrombin-antithrombin complexes, prothrombin F1+2 activation peptide, and fibrin degradation products, including fibrinopeptide A and D-dimer have been described.[31] A process of fibrin formation and degradation is continuous in the setting of many patients with malignancy. Thus cancer is often felt to be a process of "chronic DIC." It should be noted, however, that the levels of the coagulation factors and platelets are often actually elevated, not diminished as is typically noted in DIC. In two prospective studies of routine coagulation parameters in cancer patients, *elevated* fibrinogen and platelet counts were the most frequent alterations.[31] Furthermore, the increase in the levels of these two markers, observed prospectively every month, directly correlated with disease progression. The clinical spectrum of DIC in cancer varies from asymptomatic to a life-threatening thrombohemorrhagic disorder. Thrombotic manifestations of DIC include arterial and venous thromboembolism, migratory thrombophlebitis, and marantic endocarditis and microvascular thrombosis with organ failure or skin necrosis. The consumptive phase of DIC may manifest with bleeding and may respond favorably to low-dose heparin, plasma therapy, or successful treatment of the underlying malignancy. In one study of patients with prostate cancer, a clinical picture of DIC with excessive fibrinolysis and decreased levels of fibrinogen was noted.[32] In contrast to the thrombotic tendency observed in most solid tumor patients who exhibit evidence of activation of the coagulation system, the prostate cancer patients with DIC with excessive fibrinolysis did not exhibit thrombosis, and 30% died of hemorrhage.[32] When DIC is not associated with bleeding in the patient with a solid tumor, the best strategy is treatment of the underlying tumor.

With increased use of high-resolution computed tomographic imaging studies, pulmonary emboli (PEs) are increasingly being identified incidentally, in the absence of clinical suspicion. This has led to the question of how to treat these incidental PEs. Two recent studies have provided valuable guidance. A retrospective cohort study of the period from 2004 to 2010, comparing the rate of recurrent VTE and overall survival between those patients whose PEs were detected on incidental imaging studies with those whose PEs were suspected by classic clinical criteria did not identify a significant difference in these two end points.[33] A separate prospective observational study enrolling consecutive cancer patients newly diagnosed with combined deep venous thrombosis and PE from 2006 to 2009 found that 60% of the incidental thrombosis events were PEs, but only 26% of the symptomatic events were PEs.[34] This study also noted that a lower risk for recurrent thrombosis was observed in patients with incidental thrombosis compared with symptomatic thrombosis, with no differences in major bleeding and overall survival compared with symptomatic venous thrombosis patients.[34] Taken together, these two studies would support the routine anticoagulation treatment of an incidentally found thrombosis, but as always, one must balance the risks and benefits of anticoagulation.

Management of Thrombosis in Patients With Cancer

In the general population, management of venous thromboembolic disease has consisted of an acute course of heparin, or more recently a low-molecular-weight heparin (LMWH), followed by an oral vitamin K antagonist. This regimen has been the mainstay of thrombosis management since 1960, and countless patients have benefited from this treatment regimen. However, it is now well recognized that cancer

Use of Low-Molecular-Weight Heparin in Cancer Patients With Thromboses

Because of several factors, including the pharmacokinetics and varied absorption of warfarin in patients receiving chemotherapy, the use of low-molecular-weight-heparin (LMWH) in cancer patients with thromboses is suggested. In general, anticoagulation should continue as long as the patient has a hypercoagulable state. In some patients with solid tumors, this means lifelong therapy. However, the clinician should regularly reassess the risks and benefits of anticoagulation for each patient.

patients have a much higher rate of recurrent thrombosis while managed with warfarin than the population without cancer. Prandoni et al[35] compared recurrent thrombosis and major bleeding rates in thrombosis with and without cancer, managed with dose-adjusted intravenous unfractionated heparin or weight-adjusted LMWH, followed by warfarin. The 12-month cumulative incidence of recurrent thromboembolism in cancer patients was 20.7% versus 6.8% in patients without cancer, with a hazard ratio of 3.2. The 12-month cumulative incidence of major bleeding was 12.4% in patients with cancer and 4.9% in patients without cancer, with a hazard ratio of 2.2.[35]

Warfarin by its very nature is difficult to use safely and effectively in cancer patients for several reasons. There are numerous and unpredictable drug interactions. Cancer patients have variable nutritional intake, with variable vitamin K in their diets, and frequent use of antibiotics leads to highly variable bioavailability of the dietary vitamin K. Further, there is a frequent need to interrupt anticoagulation for procedures and coexisting thrombocytopenia, and the long half-life of warfarin makes these interruptions problematic. Improved treatment strategies for thrombosis in cancer have been reported with chronic use of LMWH. The seminal study was the "CLOT" study by Lee et al, published in 2003.[36] Patients with cancer and VTE received dalteparin 200 International Units/kg, subcutaneously once daily for 5 to 7 days, then randomized to either continued dalteparin 150 International Units/kg subcutaneously once daily or dose-adjusted warfarin with target international normalized ratio (INR) of 2 to 3. The hazard ratio for recurrent thromboembolism in the dalteparin group compared with the oral-anticoagulant group was 0.48, and major bleeding (6% versus 4%) and all bleeding (14% versus 19%) rates were similar. Of note, despite the marked reduction in the rate of recurrent thrombosis by the dalteparin, the overall survival rate was not affected. Based on the significant reduction in rate of recurrent thrombosis and comparable safety of LMWH compared with warfarin, this study has now established the acute and chronic use of LMWH as the standard of care for thrombosis in cancer. A similar study that compared enoxaparin with warfarin for treatment of venous thrombosis in cancer was published in 2002.[37] This study also showed an approximately 50% reduction of combined outcome of major bleeding or recurrent VTE within 3 months with enoxaparin compared with warfarin (10.5% versus 21.1%).[37] However, the study was underpowered, and the effect was not statistically significant. But the similar trend of benefit does reinforce the now-standard use of LMWH for both acute and chronic management of thrombosis in the cancer patient (see box on Use of Low-Molecular-Weight Heparin in Cancer Patients With Thromboses).

BIOLOGIC MECHANISMS UNDERLYING THROMBOSIS IN CANCER

The etiology of thrombosis is best understood in the context of the classic Virchow triad. Virchow described three classes of risk factors for thrombosis: stasis or altered blood flow, changes in the vessel wall, or changes in the blood. Cancer contributes to thrombosis by mechanisms within all three of these categories. Physical compression and/or disruption of blood vessels by a tumor may cause disrupted flow or stasis. Upon interaction with cancer cells, monocytes or macrophages release cytokines, including tumor necrosis factor, IL-1, and IL-6, which damage vascular endothelial cells.[38] The damaged vessel surface has reduced expression of naturally occurring anticoagulants, such as thrombomodulin, heparin sulfate, CD39/ecto-ADPase, nitric oxide, and prostacyclin, and increased expression of procoagulant proteins, particularly tissue factor (TF), and the blood is exposed to the procoagulant subendothelial matrix, all of which contribute to the thrombotic tendency.[38]

Tumor-Derived Tissue Factor

Despite the contributions of stasis and vessel changes in cancer-associated thrombosis, the best-documented contributing factor to thrombosis in the cancer patient is elevated procoagulant plasma factors, many of which are generated by the tumor itself. TF is the primary protein that initiates the coagulation cascade, by binding to and activating factor VII (see Chapter 128). TF is increased in a number of cancer types, including pancreatic cancer, breast cancer, and non–small cell lung cancer, compared with the nontransformed epithelium. Low oxygen levels often found in the tumor microenvironment, activation of oncogenes, such as RAS or MET, and inactivation of suppressor genes such as TP53 or PTEN directly induce TF, as well as other genes controlling hemostasis.[39] Targeting the human MET oncogene to mouse liver using lentiviral vector[40] driven by a tissue-specific promoter results in a cancer-associated coagulopathy and striking thrombotic events, which may serve as a model of Trousseau syndrome. Elevated TF expression and activation of the coagulation system correlate with both thrombotic tendency and disease progression (see later).

In addition to TF expression in tumors, activated endothelium, and tumor-associated macrophages, TF is increased in platelets and microparticles from cancer patients compared to healthy controls.[41] The generation of TF-expressing microparticles may be an important mechanism of cancer hypercoagulability. Microparticles are vesicular structures released from cell membranes under a range of situations, including activation, malignant transformation, stress, or death and are detected in plasma in a wide range of disease states, including sepsis and cancer.[42] There is no precise definition of the size and nature of microparticles, but they are generally considered to be between 100 nm and 1000 nm in diameter. Microparticles have been reported to arise from platelets, monocytes, endothelial cells, and tumor cells and carry on their surfaces a range of proteins that derived from the cell of origin, including TF. Cancer cells, directly and indirectly, lead to the generation and circulation of TF-bearing microparticles, and the levels of circulating TF-bearing microparticles in pancreatic cancer patients strongly correlates with the subsequent risk for venous thromboembolic disease. In one recent report, 34.8% of patients with detectable TF-bearing microparticles developed venous thrombosis, compared with no thrombosis in those without detectable TF-bearing microparticles.[42]

Coagulation's Role in Tumor Progression

Although the interplay between the coagulation pathway and cancer is best appreciated to result in an increase in thrombosis in cancer patients, the activation of coagulation in cancer may also play a role in tumor progression. For example, TF expression levels often correlate with a more aggressive tumor phenotype, and both clotting-dependent and clotting-independent signaling mechanisms of TF may be important in regulating tumor metastasis.[43] TF promotes angiogenesis and coexpresses with VEGF on malignant cells. Each is also able to upregulate the other. Interestingly, TF and VEGF knockout mice are embryologic lethal at the same stage with a similar phenotype, disorganized yolk sac vasculature,[44,45] implying functions that are overlapping.

Thrombin not only is the key terminal enzyme of coagulation resulting in fibrin deposition and platelet activation but also is a

growth factor for a number of cell types such as fibroblasts, endothelial cells, smooth muscle cells, and tumor cells. The cellular effects of thrombin are mediated through seven transmembrane-spanning G protein–coupled protease-activated receptors (PARs), principally PAR1. PAR1 is activated by thrombin through cleavage of its N-terminal, which exposes a tethered ligand that then binds to the second transmembrane domain of the receptor. PARs are expressed on platelets and other cells, as well as on tumor cells and human tumor specimens.[43] Thrombin-activated tumor cells have PAR1-dependent enhanced expression of multiple integrins. Thrombin may enhance tumor progression by several mechanisms, including enhancing tumor cell proliferation; activating tumor-platelet adhesion; tumor adhesion to the matrix or endothelium; tumor implantation, growth, and metastasis; and tumor angiogenesis.[43] Thrombin alters tumor cell gene expression with upregulation of angiogenesis-related genes such as VEGF, VEGFRs, matrix metalloproteinase 2 (MMP-2), angiopoietin 2 (ANG2), and other genes and micro-ribonucleic acids (miRNAs) affecting tumor cell proliferation and invasion such as SKP2, Twist, cathepsin D, and growth-regulated oncogene-α (GRO-α).

Platelets and Cancer

In addition to the abnormalities in platelet number seen in cancer, described earlier, platelet function has been noted to be altered in cancer, and these alterations may contribute to tumor progression. Platelets derived from cancer patients are activated as measured by increased surface P-selectin expression and elevated serum levels of platelet factor 4 and β-thromboglobulin. Not only may the activation of platelets contribute to coagulation abnormalities seen in cancer patients (see later), but activated platelets can interact with leukocytes, endothelial cell as well as tumor cells, and contribute to the early stages of tumor cell dissemination. Visualization of tumor cells arrested in the pulmonary vasculature reveals interaction with platelets and fibrinogen, and in fact the ability of tumor cells to aggregate platelets in vitro correlates with metastatic potential.[46] In blood-borne models of hematogenous metastasis, platelets are necessary for efficient metastasis.[47] In these classic studies platelet reduction by antiplatelet antibody markedly reduces experimental hematogenous metastasis. The importance of platelet number and function in metastasis was confirmed by more recent studies in NF-E2$^{-/-}$ mice that have few circulating platelets, in mice whose platelets are rendered nonfunctional by knockout of Gαq$^{-/-}$, and in PAR4$^{-/-}$ mice that are unable to respond to thrombin.[48]

A number of platelet receptors may contribute to the platelet support of metastasis, including GPIIb/IIIa, adenosine diphosphate (ADP) receptors, P-selectin and thrombin receptors, and others, and there are likely multiple mechanisms underlying the platelet effects on malignancy[48]. (1) Platelets stabilize otherwise short-lived tumor cells in the circulation; (2) Platelet–tumor cell interaction enhances tumor cell adhesion to the vessel wall and results in distal embolization and downstream ischemic endothelial damage; (3) Platelets in the vicinity of tumor cells alter vessel wall permeability and tumor cell invasion; (4) Platelets protect tumor cells from immune surveillance and destruction, in part by shielding tumor cells from natural killer cells, although other mechanisms are likely; (5) Platelets provide nutrient support (growth factors) and release proangiogenic factors. Platelets contain numerous growth factors, coagulation factors and adhesive molecules, chemokines, and bioactive lipids that may enhance metastatic efficiency. Platelets are enriched in angiogenic growth factors such as basic fibroblast growth factor and VEGF, as well as several inhibitors, and may regulate angiogenesis, which is a hallmark of malignancy. Selective P-selectin and thrombin receptor activation on platelets may release α-granules enriched in either VEGF or endostatin; (6) Platelet-derived transforming growth factor-β and direct platelet–tumor cell contacts promote epithelial mesenchymal transformation and tumor metastases; (7) Platelet activation by tumor cells provides a surface for local thrombin generation.

FUTURE DIRECTIONS

Future research on the interplay of cancer, hematopoiesis, and coagulation not only will provide effective therapies for the hematologic manifestations of cancer, but also will provide insight into the biology of tumorigenesis and may lead to new strategies to treat cancer. For example, understanding how the use of exogenous erythropoietin may promote tumor survival and/or growth may lead not only to a better appreciation of which tumors may be more sensitive to this untoward effect (e.g., localized versus metastatic, tumors expressing the erythropoietin receptor versus tumors not expressing this receptor), but to novel agents that bypass this effect and even to agents that can disrupt this signaling and have antitumor effect. Better understanding of the role that platelets and/or thrombin play in tumor promotion may one day lead to an effective antitumor strategy that incorporates antiplatelet or antithrombotic agents.

CHAPTER 158

INTEGRATIVE THERAPIES IN PATIENTS WITH HEMATOLOGIC DISEASES

David S. Rosenthal, Kara M. Kelly, and Donald I. Abrams

Complementary and alternative medicine, more popularly known as CAM, is tremendously popular in the United States and many parts of the world in helping people deal with wellness and health concerns.[1] In the United States alone, an estimated $36 to $47 billion is spent annually by the public on CAM methods of therapy,[2] and in a National Health Interview Survey in 2007, 37% of adults used at least one form of CAM. Over the past decade, CAM practices have become even more popular, especially in individuals with a chronic disease such as hematologic malignancies and cancer.[3] The National Center for Complementary and Alternative Medicine (NCCAM) at the National Institutes of Health studies the efficacy and safety of CAM practices.

Unfortunately, the term *CAM* causes consternation in many of our professional colleagues who perceive that their patients are forgoing conventional therapy. That is generally not the case. The term *CAM* is controversial because the words *complementary* and *alternative* have completely different meanings and should not be connected by an "and" but by an "or." Whereas complementary therapies as defined by NCCAM are therapies used to complement or to be used *alongside* conventional methods of therapy, alternative methods refer to those therapies that are used *instead* of known conventional therapies and have not been shown to be effective. The term *integrative medicine* (IM) is used to more accurately describe the complementary therapies being used in U.S. medical settings today. These therapies are used alongside conventional therapies in a therapeutic environment.

Integrative therapies is the term used in this chapter. The components of IM include (1) combining the best of both conventional and evidence-based complementary therapies, (2) emphasizing patient participation, (3) promoting the primacy of the patient–provider relationship and the importance of shared decision making, (4) emphasizing the contribution of the therapeutic encounter itself, and (5) optimizing the individual's innate healing capacity.[4a] In contrast, alternative medicine includes therapies such as the use of laetrile or amygdalin, which are proven to be toxic and ineffective.

Although many integrative therapies such as acupuncture, massage, and meditation are quite beneficial for cancer patients by helping them to cope with the disease, reducing their stress and symptoms related to conventional therapy or to the disease process itself, many interventions are unproven and could be harmful for patients who may believe that these interventions can cure them of their malignancy. An American Cancer Society study concluded that as many as 61% of cancer survivors used some form of complementary or alternative therapies.[3] Unfortunately, the majority of people do not share this information with their primary care providers. According to a survey by Eisenberg et al,[4b] patients do not think that their physician needs to know about their usage of these interventions or the physician never asked about such use. Because there are many potential drug–drug, drug–herb, drug–radiation, and antioxidant–drug interactions, it is extremely important for patients to share their use of integrative therapies and alternative treatments with their providers and similarly for physicians to ask about their patients' usage.[5]

Through the NCCAM and IM centers, more information and education has been going out not only to the public but also to physicians, alerting both groups to the importance of physicians' "asking" about the use of integrative therapies and alternative therapies and patients "telling" about the use of these therapies (http://www.nccam.nih.gov). Many hematology/oncology centers have established IM programs where complementary therapies such as acupuncture, massage, nutrition, physical activity, and stress management are offered alongside conventional therapies such as chemotherapy and radiation. These programs provide guidance to patients in choosing the safest and most effective integrative therapies to incorporate into their plans of care.

Despite the level of evidence supporting standard treatment, some patients still do not want chemotherapy, radiation, or surgery. Instead, they choose to pursue an alternative therapy. Sometimes this choice is because of cultural belief, because they believe that natural products are potentially less toxic, or because they believe that the alternative treatment will offer a "cure" for their disease. Alternative medicine practitioners and clinics exist in our country and around the world that, usually for a significant amount of out-of-pocket fees, suggest that they can offer a "cure" for individuals' hematologic malignancies. Unfortunately, these clinics rarely ever provide any evidence that they are curing disease and typically do not conduct research or report their results except in advertisements.

There is small but increasing body of research on the benefits of many integrative practices. Clinical studies provide evidence that some integrative therapies are beneficial to patients by improving their quality of life and reducing their symptoms from the disease and side effects from treatment. Research on botanicals and herbs is often aimed at efficacy and safety.

Clinical studies demonstrate concerns regarding the safe use of some botanicals in conjunction with chemotherapy and radiation therapy. Some may reduce the effectiveness of certain chemotherapies, and others may reduce metabolism of an active drug, enhancing its potential toxicity.

INTEGRATIVE THERAPY DOMAINS AND THEIR USE

The four major categories of integrative therapies include mind–body approaches, energy-based therapies, body-based manipulative therapies, and natural products (Table 158-1). There is also an abundance of whole-systems practices that include ayurvedic medicine, naturopathy, homeopathy, and traditional Chinese medicine. The whole-systems approaches incorporate many of the above integrative therapies. Mind–body approaches include meditation, mindfulness meditation, guided imagery, music therapy, creative arts therapy, self-hypnosis, yoga, tai chi, and qigong, among many other types of spiritual practices. Energy-based therapies include reiki and healing touch. Body-based manipulative therapies include chiropractic and massage therapy. Examples of natural products include dietary supplements, antioxidants, herbs, and botanicals.

In the literature, there is a paucity of information on the use of integrative therapies in the treatment of hematologic malignancies.[6] In India, there is a significant use of ayurvedic medicine. In a German study of a large group of chronic lymphocytic leukemia (CLL) patients, approximately 44% used integrative therapies with 26%

• Body based or manipulative	• Ayurvedic
• Natural products	

using vitamin supplementation, 18% mineral supplementation, 14% homeopathy, 7% acupuncture, and 9% mistletoe therapy. In the United States, 30% to 80% of pediatric hematology/oncology patients used one or more complementary therapies in conjunction with their conventional care. In the U.S. pediatric group, there is an especially high use of vitamin and nutritional supplements,[6,7] with mind–body therapies a close second. Because many patients do not report their use of complementary therapies to their primary care hematologist/oncologist, there is markedly disparate data from one study to another. In a review by Wesa and Cassileth,[8] the major reason why leukemia patients use integrative therapies or remedies not prescribed by their hematologist/oncologist is in an effort to improve their treatment outcome and to manage their symptoms. For those with leukemia, the integrative therapies that were most beneficial included mind–body interventions such as self-hypnosis, meditation, guided imagery, and breath awareness. Massage and reflexology are also frequently used to decrease symptoms (see discussion of massage below). Acupuncture is very beneficial for symptom management with minimal side effects (see discussion of acupuncture below).

RESEARCH TECHNIQUES OF INTEGRATIVE THERAPIES

Over the past several years, there has been a gradual increase in research in the United States on integrative therapies. Supported by the National Institutes of Health (NIH) thru NCCAM and Office of Cancer Complementary and Alternative Medicine at the National Cancer Institute, investigators have often tried to apply the same research principles used to evaluate new chemotherapy programs for leukemias and lymphomas (i.e., the traditional randomized clinical trial).[9] This approach has been problematic because it is often difficult to identify the proper controls for integrative therapies such as mind–body techniques, acupuncture, and massage. As a result, meta-analyses on integrative therapies reveal an abundance of pilot studies and nonrandomized clinical studies that are criticized on the basis that any positive result may be attributable to the placebo effect.[10] In the case of acupuncture, practitioners have used sham or "fake" acupuncture as a control in which nontraditional needles are not placed in the meridian spots and not stimulated.

In randomized clinical trials of acupuncture effectiveness, comparing active acupuncture with "sham" or acupuncture, only those who are naïve to acupuncture can participate. With massage therapy, randomized clinical trials have used an educational program of equivalent attention time to attempt to control for the placebo effect. This has been similarly true for research on reiki and many of the mind–body programs.

Whole-systems research is another approach taken by integrative therapists.[10] This involves combining nutrition, physical activity, and stress and symptom management therapies together as an intervention in determining quality of life measures over a period of time. This type of research creates many variables and is totally contrary to the current widely accepted reductionist method of research.

The study of herbs and other over-the-counter (OTC) unregulated products has been fraught with confounding variables, including the standardization of the product studied.[11] For example, PC-SPES, an eight-herbal compound manufactured by a single company, was demonstrated in a pilot study in men undergoing active surveillance for prostate cancer to be associated with a decrease in their prostate-specific antigen levels. The promising trends of this phase I and later a phase II study led to a randomized clinical trial of PC-SPES. During the phases of this randomized clinical trial, there were complications that led to the reevaluation of the constituents of PC-SPES. Previous evaluations showed no evidence of any phytoestrogens in any of the eight herbal compounds, but during the randomized clinical trial, phytoestrogens were found, and patients began to demonstrate breast engorgement. Other lots did not contain phytoestrogens but were demonstrated to have contaminants such as dicoumarol, and individuals taking them were noted because of their increased bruisability. Investigators have attempted to overcome the standardization issue of herbs by studying individual proteins in in vitro models, and others have attempted to closely monitor the constituents of the herbs by protein fractionation, ensuring that the product remains constant during the research study. Most herbs and botanicals are not regulated by the U.S. Food and Drug Administration, potentiating issues of quality control, possible contamination, and stability issues. The United States Pharmacopeia (USP) does verify the identity, strength, purity, and quality of some supplements and applies its USP verification label (http://www.usp.org/uspverified).

REVIEW OF RESULTS OF INTEGRATIVE THERAPIES IN HEMATOLOGY/ONCOLOGY PATIENTS

Most studies on the use of integrative therapies in hematology/oncology disorders have been used to investigate the effect on patients' general quality of life and symptomatic relief of stress, pain, fatigue, and anxiety. The results discussed here will be reviewed in terms of improvement in symptoms and quality of life, and when appropriate, the effect on immune function and survival if investigated. In most studies, the major symptoms for which integrative therapies are used include anxiety, fatigue, pain, chemotherapy-induced nausea and vomiting (CINV), worsening immune system, stress, and depression.

Literature on Outcomes: Science, Safety, and Efficacy

In making decisions about what integrative therapies physicians should recommend, Weiger et. al[12] suggest that decisions be based on safety and efficacy. If an intervention is safe and effective such as acupuncture for CINV, it can be appropriately recommended. If a therapy is unsafe or toxic and has been demonstrated to be ineffective, it should not be recommended, and patients should be cautioned about its use. For example, laetrile (Amygdalin), which contains varying amounts of cyanide, is toxic and in studies has been shown to be ineffective in treating disease.

In addition, many interventions, products, and substances are safe, but their effectiveness is unknown. With these, the physician should be cautious and recommend their use with the following proviso. If this is a substance taken orally, it should be evaluated as to whether it has any unfavorable interactions with chemotherapy or medications that the patient is already taking or whether it interacts with a disease process such as causing hypoglycemia in a diabetic patient. Taking one new OTC substance at a time is common sense, and patients should be told to observe any change in symptoms, whether they are favorable or unfavorable, before adding another substance to their oral regimens. With respect to drug–drug and drug–herb interactions, websites are available for professionals as well as for individual patients. A list of these websites is given in Table 158-2. Most of these websites list the various terms by which a given agent is known and provide information on each agent's constituents, reasons for use, evidence for safety or toxicity, and evidence of effectiveness. Most importantly, these websites list the adverse effects of these substances and the drug–drug, drug–herb, and drug–disease interactions when known. When asked about the use of an OTC substance that is not FDA regulated, physicians should consult one of the databases to ensure safety and lack of adverse interactions (see Table 158-2).

INDIVIDUAL INTEGRATIVE THERAPY MODALITIES

Mind–Body Therapies

Mind–body therapies are frequently studied interventions in patients with chronic diseases such as hematology/oncology malignancies.[13,14] Stress is part of normal physiologic body function and can be subdivided into good stress and bad stress. Chronic stress can be caused by an unexpected situation one is faced with such as experiencing a new diagnosis (e.g., leukemia), an uncomfortable interaction with a colleague, or the loss of a job. Chronic stress has been shown to decrease immune function, perhaps through the mechanism of decreasing natural killer (NK) cells and impairing the effectiveness of DNA repair. In the 1970s, Dr. Herbert Benson popularized the "relaxation response," the performance of "a time out" in normal daily functions. Benson coined this term after observing that when monks meditated, they experienced decreases in their pulse, blood pressure, and respirations. Although there are now known genetic, environmental, and dietary factors that play a significant role in causation of chronic disease, stress may be a lesser but significant factor. Frequently studied, mind–body techniques (Table 158-3) include meditation or the relaxation response, mindfulness meditation, guided imagery, and hypnosis. In addition, music therapy, physical activities such as yoga, tai chi, and chi gong also are related mind–body programs.

There are three common forms of meditation: (1) concentrative meditation, which focuses on a phrase or a visual image such as the relaxation response; (2) mindfulness meditation or awareness, in which the client becomes aware of his or her thoughts and feelings and focuses on those issues; and (3) expressive meditation used in tribal societies consisting of fast deep breathing, shaking, whirling, and dancing.[13]

Mind–body interventions are often self-taught or presented by a professional. Double-blinded trials are difficult to conduct partly because the presence of an empathetic professional giving the therapeutic modality may be considered a placebo effect. Mind–body interventions are often accompanied by other integrative therapy interventions, making pure studies unevaluable; however, randomized clinical trials have demonstrated that relaxation training and guided imagery significantly reduce nausea and anxiety.[14a]

Compared with medication, relaxation therapy showed similar decreases in anxiety and depression, although medication might have been slightly faster in its effect. Other randomized trials have shown decreases in tension, depression, anger, and fatigue during relaxation training or imagery. In children, hypnosis has been found to be especially effective. In a randomized clinical trial comparing hypnosis or nonhypnotic distraction such as the relaxation techniques versus joining a placebo attention control group, the children in the hypnosis group reported significant reduction in anticipatory and CINV.

Mind–body therapies have also been used to alleviate pain. In a study of children undergoing bone marrow or lumbar puncture procedures, hypnosis significantly reduced the pain as well as anxiety. In a randomized clinical trial examining the effects of the relaxation response therapy (RRT) versus reiki therapy in men being treated with external-beam radiotherapy for prostate cancer, RRT improved emotional well-being and eased anxiety, and reiki therapy had a positive effect on anxiety. Expressive arts therapy and music therapy as well as repetitive exercise, yoga, tai chi, qigong, and Pilates also can reduce stress and anxiety.

Music therapy is considered a mind–body therapy that reduces stress and anxiety because it uses a variety of active and passive music experiences, live or recorded. This technique can be used either independently or with a music therapist. Randomized trials have shown statistically significant improvements in mood and physical discomfort. In patients with hematologic malignancies admitted for autologous stem cell transplantations, patients receiving an individualized program of live music therapy had a significant improvement in mood. Music therapy has also been shown to be an effective adjunct to antiemetic therapy. Studies of immune function have yet to show any statistically significant improvement in immune function.

Yoga and physical activity have been studied to determine whether there is a related reduction in symptoms of depression and anxiety. In a 12-week yoga intervention in healthy subjects, it was demonstrated that there was greater improvement in mood and anxiety than a metabolically matched walking exercise. The authors demonstrated an acute increase in thalamic GABA (γ-aminobutyric acid) levels alongside the improvement in mood and anxiety scales. White et al[14b] demonstrated the potential benefits of physical activity for children with acute lymphocytic leukemia.

Mind–body therapies can reduce anxiety, temper the adverse effects of chemotherapy and radiation treatments, relieve pain, and possibly stimulate immune responses. By reducing stress and anxiety, these therapies can help patients deal with a wide range of relationship issues and decision making as they move through the diagnostic and therapeutic phases of their malignancy. Mind–body approaches have very minimal risk and potentially significant benefits. Most importantly, they are often self-taught and therefore low cost. Anderson and Taylor[14c] reviewed three clinical trials addressing the use of mind–body therapies for management of the metabolic syndrome as defined by an increased risk of type II diabetes, cardiovascular disease, and other chronic conditions. Findings in these studies support the potential clinical effectiveness of mind–body practices in improving indices of the metabolic system. Mind–body practices should be considered as an adjunct to usual care regardless of whether patients are beginning or recovering from chemotherapy.

Acupuncture

Overview and Definitions

One of the major components of traditional Chinese medicine has been the use of acupuncture. For more than 2.5 millennia, this traditional practice has been used in the Far East to "correct

an imbalance in yin-yang and qi [energy]." It is believed that with acupuncture, "blocked" channels can be unblocked, reducing symptoms. Acupuncture is the stimulation of certain points on the body by a needle or alternatively by pressure called acupressure. Both techniques take advantage of the meridians described by traditional Chinese medicine. Acupuncture points are situated along meridians, which are channels for "qi." Sham or "fake" acupuncture implies the use of needles that are not inserted to the same depth, not put in the meridian points, and not given stimulation. Electroacupuncture implies the use of added electrical pulses to create additional or accentuated stimulation. Several studies have shown that electroacupuncture provides greater symptom relief than regular acupuncture.

Research on Usage and Effectiveness

Most acupuncture in the Western world is used to manage symptoms, not treat disease.[15] Research studies have demonstrated release of neurotransmitters and change of brain functional magnetic resonance imaging signals during acupuncture. Acupuncture was confirmed as an effective intervention for CINV at an NIH consensus conference in 1997. Whether this beneficial effect is attributable to an induced relaxation response or a direct antiemetic effect is not known.

Randomized clinical trials on acupuncture have been used in a variety of settings. As mentioned earlier, only individuals who are naïve to acupuncture can take part in acupuncture studies because they will note the difference between active acupuncture and its sham component. Acupuncture has been shown to be effective in randomized clinical trials in cancer-related fatigue, cancer-related pain, and postoperative pain as well as reduced CINV.

Several randomized clinical trials conducted in China have suggested that acupuncture could be effective in reducing the marrow suppression in patients on aggressive chemotherapy. Analysis of these trials performed by Lu et al[16] suggest that acupuncture is associated with an increase in neutrophils and total white blood cell count in patients during chemotherapy or chemoradiation therapy. The weighted mean difference of over 1000/μL white blood cells on average is a statistically significant difference. Lu et al[17] carried out a small, randomized, sham-controlled clinical trial in the United States exploring this issue in ovarian and breast cancer patients receiving aggressive chemotherapy. In a pilot randomized, sham-controlled trial using manual and electrostimulation two to three times per week for a total of 10 sessions beginning 1 week before the second cycle of chemotherapy, the media leukocyte count in the active acupuncture arm at the first day of the next cycle was significantly higher than in the sham arm. The median leukocyte nadir, neutrophil nadir, and recovering absolute neutrophil counts were all higher but not statistically different. The result showed improved neutrophil count both at the nadir and rebound points during chemotherapy, but the study was not statistically significant and was underpowered.

Uncontrolled pilot studies of acupuncture have shown effectiveness in reducing anxiety and improving mood and other quality of life measures in patients with both oncologic and hematologic disorders. These studies have also shown improvement in sleeplessness, depression, and xerostomia. Acupuncture enhanced xerostomia inventory scores in 18 patients who received radiation therapy and had pilocarpine-resistant xerostomia. However, a randomized clinical trial failed to show any significant difference between active acupuncture and sham acupuncture in xerostomia. In patients with hot flashes and vasomotor symptoms caused by chemotherapy, acupuncture attenuated some of the hot flashes. In a controlled study comparing venlafaxine and acupuncture, no statistical difference was found between the favorable response to acupuncture and the medication.

Safety

With the increasing use of acupuncture in the United States because of evidence of its effectiveness, there are concerns about its safety when used in the community, especially with hematology patients and those getting chemotherapy and radiotherapy. However, reports of major side effects of acupuncture are rare and usually are evident when performed by untrained practitioners. In closely monitored clinical trials, there is a low incidence of adverse events. In one study, the rate of minor adverse events was 14 per 10,000 sessions; serious events were 0.05 per 10,000 treatments and 0.55 per 10,000 individual patients. Common adverse events include bloodborne infections and internal organ and tissue injury. Generally, acupuncture should be avoided in patients with severe neutropenia and thrombocytopenia (absolute neutrophil count <500/μL and platelets <25,000/μL). However, in one study of acupuncture given during stem cell transplantation, there were no bleeding side effects in individuals with severe thrombocytopenia (platelet counts <20,000/μL). Currently in the United States, there are several schools of traditional Chinese medicine emphasizing the practice of acupuncture. These are 3- to 4-year certificate programs well versed not only in understanding effectiveness but also safety.

Massage and Touch Therapies

Overview and Definitions

Massage has been defined by some as "rhythmic and methodical stretching and compressing of the muscles and connective tissue through the touch of the therapist's hands." There are many types of massage and hands-on soft tissue therapies (Table 158-4). Therapies include Swedish massage, aromatherapy massage, reflexology, acupressure, and manual lymphatic drainage massage. Swedish massage provides broad, flowing, soothing strokes (effleurage) generally applied with a lotion or massage oil from distal to proximal areas on extremities. In addition, there is usually gentle kneading of soft tissues (petrissage). Aromatherapy has often been combined with massage in which selected scented oils are blended with the usual massage oil to enhance the beneficial effects of both physical and emotional well-being. Reflexology focuses on manual pressure to specific areas of the feet that, in traditional Chinese medicine, are linked with remote areas of the body. Acupressure massage uses the meridian theory of traditional Chinese medicine in which focal pressure is applied to acupuncture needle sites with the goal of adjusting the flow of energy similar to the theory in acupuncture. Manual lymphatic drainage is the application of light, flowing strokes of massage in specific patterns with the goal of alleviating lymph edema after lymph node resection or radiation therapy.

Research on Usage and Effectiveness

Corbin[18a] has reviewed the value of massage as well as the difficulties in performing scientific research. Many randomized clinical trials use a cross-over arm and attempt interventions that try to control for the placebo effect. The various measurement tools used to assess outcomes involve numerical rating scales, visual analog scales, profile of mood status, the S state trait anxiety inventory, the European Organization for Research and Treatment of Cancer quality of life

questionnaire, and so on. In a critical review of potential benefits of massage, Joske et al[18b] identified eight randomized controlled clinical studies in hematology/oncology patients totaling more than 357 patients. Specifically, there was evidence of anxiety reduction with less benefit for analgesia. In autologous bone marrow transplantation patients, the massage group had significantly decreased distress and nausea scores early on in the trial, but these were not long standing. Massage therapy has been found to reduce state anxiety in many meta-analyses, probably its most beneficial attribute. Pain may be alleviated, but this has not been demonstrated to be statistically significant. Numerous studies have shown trends not only in decreased anxiety but also in nausea, pain, fatigue, and depression.

To date, there is little evidence suggesting that massage therapies have any effect on immune function or survival outcomes in hematology/oncology patients. A small randomized study did find higher NK cells and lymphocyte cells in a massage. Similarly, in a study in HIV patients, there was a significant increase in NK cell fighter toxicity during the massage period. In some trials, there is a short-term effect on NK cell activity; however, long-term clinical effect has not been demonstrated. A significant effect of effleurage massage on cellular immunity, cortisol, oxytocin, anxiety, depression, or quality of life also has not been demonstrated in more rigorous randomized clinical trials. In another randomized clinical study, dopamine levels, NK cells, and lymphocytes increased from the first to last day of the massage therapy. In a study of children with HIV, a control arm had a greater relative risk of CD4 count decline than the massage therapy children. Lymphocyte loss was also more extensive in the control participants, and more of the control group than the massage group lost greater than 50/mm^3 CD8 lymphocytes. The immediate effects of massage therapy are decreased anxiety, depressed mood, and anger. The long-term effects of massage include reduced depression and hostility as well as increased urine meridopamine, serotonin values and NK cell number, and lymphocytes. However, it is not clear that these results were statistically significant.

Weaknesses exist in many of the massage therapy studies reported to date such as small sample sizes and lack of controls. Most of the practitioners have not been blinded to the hypothesis of the studies. Furthermore, no systematic approach has been identified to determine the optimal number of massage treatments in a trial and within-group comparisons. Strong evidence shows that massage therapy can be very helpful in alleviating anxiety and stress in patients. However, more rigorous study designs, adequate statistical power, better identification of predictors for response to massage, and study of the psychologic and biologic mechanisms are needed. There is also a need for larger sample sizes and rigorous design reporting on massage therapy.

Safety

The concern that massage therapy can spread a tumor is unfounded. However, direct pressure over known tumor sites is usually discouraged. In general, massage therapy of all types is quite safe.

Nutrition and Supplements

Nutrition

Nutritional guidelines for patients with hematologic malignancies should be based on the recommendations of the American Cancer Society and the American Institute for Cancer Research (AICR)/World Cancer Research Fund.[19] The AICR clearly states that cancer survivors should follow its nine nutrition and physical activity guidelines for risk reduction. The first recommendation is to be as lean as possible without being underweight. Although hematologic malignancies are not among those listed as being most associated with obesity (breast, esophagus, pancreas, gallbladder, colorectal, endometrial, and kidney), a review suggests that being overweight or obese probably does increase the risk of non-Hodgkin lymphoma (NHL), diffuse large B-cell lymphoma, follicular lymphoma, and CLL, although results are inconsistent among studies. In general, because obesity is related to increased inflammation and decreased immune function, it is best for patients with hematologic malignancies to aim to maintain a body mass index of less than 25.

The second AICR recommendation is to be physically active for 30 minutes every day. Although few studies have evaluated physical activity and hematologic malignancies, data suggest that low physical activity may increase the risk of NHL and increasing activity may reduce the risk, especially for follicular and small lymphocytic lymphoma.

The third recommendation is to avoid sugary drinks and limit consumption of energy-dense foods. This is obviously linked with the body weight guideline because sugary drinks contribute many empty calories to the standard American diet. In addition, the contribution of insulin and insulin-like growth factor type 1 to the development of malignant disease is being increasingly appreciated in a number of cancers, leading to the investigation of blockade of the insulin-like growth factor 1 receptor as a novel treatment for some malignant diagnoses.

Fourth, the AICR suggests that people eat a greater variety of fruits, vegetables, whole grains, and legumes such as beans. Data from the U.S. Centers for Disease Control and Prevention demonstrate that the American public falls far short on the conservative recommendation to consume at least five servings of fruits and vegetables daily with only 14% of adults meeting the guideline. Plants are rich sources of fiber, antioxidants, and phytonutrients, many of which are believed to be useful in cancer risk reduction. In one study, dietary fiber intake was associated with a lower risk of all NHL subtypes. Another analysis found that high consumption of fruits and vegetables was associated with a lower risk of all NHL subtypes, particularly follicular lymphoma, in women but not men.[20]

Fifth, the AICR recommends limiting consumption of red meats (beef, pork, and lamb) and avoiding processed meats. Epidemiologic studies suggest that consumption of fried red meats as well as dairy products leads to an increased risk of NHL.[20] Conversely, consumption of higher levels of omega-3 or marine fatty acids has been shown to be inversely correlated with lymphoma risk. Additional studies suggest that a diet high in fish may also be protective against the development of other hematopoietic malignancies—leukemias and multiple myeloma as well as NHL—in an Australian cohort.[21]

Sixth, the AICR guidelines state that if consumed at all, alcoholic drinks should be limited to two for men and one for women per day.

Although moderate alcohol consumption may be associated with cardiovascular benefits, alcohol use has been associated with an increased risk of a number of malignancies. A pooled analysis of nine case-control studies of NHL revealed that ever drinkers, compared with never drinkers, had a 17% lower risk of NHL, a finding the investigators attributed to a possible beneficial effect of moderate alcohol consumption on immune function. A cohort study in 126,293 multiethnic adults used lifelong abstainers and infrequent drinkers as the referent and reported a relative risk of 0.5 for the development of both lymphocytic and myeloid leukemias in those consuming three or more drinks daily without any contribution of choice of beverage (wine, beer, or liquor). With regards to patients already diagnosed, a cohort of 575 female NHL cases in Connecticut was followed for a median of 7.75 years. Compared with never drinkers, wine drinkers experienced better overall survival (75% vs. 69% five-year survival; $P = .030$) and disease-free survival (70% vs. 67%; $P = .049$). The favorable effect for wine drinkers was seen mainly in patients with diffuse large B-cell lymphoma. Resveratrol, a red wine polyphenol known for its potential cardioprotective effects, is also believed to have potential in cancer risk reduction and perhaps even as an adjunct to conventional therapy. An in vitro study involving acute lymphoblastic leukemia (ALL) cell lines demonstrated that red wine polyphenols caused growth inhibition and apoptosis. Although these cell line experiments often produce elegant results regarding mechanism of observed in vitro action, whether the phytonutrients have the same benefits in humans consuming the whole foodstuffs or concentrated supplements remains uncertain.

Supplements

Most conventional medical and radiation oncologists recommend that their cancer patients avoid all supplements, especially during active radiation and chemotherapy. This recommendation is primarily based on the absence of convincing data supporting therapeutic benefit. Three other valid concerns about supplement use are (1) the potential for supplement–drug interactions via a pharmacokinetic or pharmacodynamics pathway; (2) the oxidant–anti-oxidant issue; and (3) the impact of supplements on clotting, a particular problem for patients with hematologic malignancies on or off anticoagulants.

Concurrent use of a supplement, particularly a botanical, with chemotherapy could lead to a clinically important interaction that could yield an increase or decrease in the effects of either component. Considering that 35% of currently prescribed oncology drugs are metabolized by the CYP3A4 isoform of the hepatic cytochrome p450 enzyme system, use of supplements that either induce or inhibit the pathway can be problematic.[22] In treatment of hematologic toxicities, cyclophosphamide, the epipodophyllotixins, and the vinca alkaloids are all dependent of CYP3A4 for their metabolism. For example, the botanical supplement St. John's wort used for the treatment of mild depression is a strong inducer of many CYP isoforms. In a classic pharmacokinetic interaction study, 10 healthy volunteers were administered a single 400-mg oral dose of imatinib before and after 2 weeks of treatment with 300 mg of St. John's wort three times daily. The investigators found that the pharmacokinetics of imatinib were significantly altered by St. John's wort, with reductions of 32% in the median area under the concentration-time curve ($P = .0001$), 29% in maximum observed concentration ($P = .005$), and 21% in half-life ($P = .0001$). The conclusion was that coadministration of St. John's wort might compromise the clinical efficacy of imatinib. It is generally recommended that cancer patients receiving any intervention avoid taking St. John's wort.

Patients with hematologic malignancies are often at increased risk for bleeding problems. There has been a long-standing tendency to attribute thrombocytopenias of unclear etiology in cancer patients to botanical supplements that they are taking, particularly traditional Chinese medicine herbs. Warfarin is a frequently prescribed anticoagulant, itself derived from a botanical, which can be impacted in a number of ways by diet and dietary supplements. Inappropriate control of anticoagulation because of fluctuation in warfarin effect exposes the patient to risks of increased bleeding or thromboembolic complications. Warfarin is metabolized by the cytochrome p450 system isoforms, including CYP3A4. In addition, it is also highly protein bound and hence can interact with medications or supplements that are also highly protein bound, resulting in displacement and causing increases in international normalized (INR) ratio and necessitating warfarin dose reduction. Finally, the anticoagulant effect of warfarin can be antagonized by vitamin K intake. Patients prescribed warfarin are often advised not to eat green leafy and cruciferous vegetables or to consume green tea because they are rich in vitamin K and might interfere with the anticoagulant effect. An alternative is to allow the patient to consume a healthful diet and adjust the warfarin dose accordingly to maintain the desired INR.

Omega-3 Fatty Acids

Omega-3 fatty acids have been reported in isolated cases to potentiate the anticoagulant effects of warfarin. Omega-3 fatty acids may lower thromboxane A(2) levels within the platelet as well as decrease factor VII levels. These factors, which make the omega-3s attractive as anti-inflammatory and cardiovascular agents, need to be borne in mind in patients on warfarin therapy. Taken in the absence of warfarin, omega-3s are not believed to be a significant cause of bleeding at doses of less than 4000 mg/day. Epidemiologic data suggest an inverse relationship between the intake of marine omega-3 fatty acids and the development of a number of hematologic malignancies and the good risk-to-benefit profile.

Vitamin D3

Vitamin D is one of the few remaining vitamins that has not been shown to be ineffective in protecting against malignant disease. An ongoing randomized clinical trial is currently looking at a two-by-two factorial design of omega-3 fatty acids and vitamin D3 supplementation in older adults to assess cancer risk reduction, among other endpoints. At the same time, increasing evidence suggests that vitamin D deficiency may be related to the risk of a number of solid tumors, particularly breast, colon, prostate, and pancreas. An inverse relationship has been described between the development of NHL and sun exposure, particularly recreational, non-occupational sun exposure. One proposed explanation for this unexpected finding is that sun exposure is actually a surrogate marker of vitamin D status, and it is actually vitamin D sufficiency that is protective against lymphoma.[23] In a meta-analysis of eight studies to date, the investigators found no conclusive evidence that vitamin D was providing the observed benefit, although serum levels were not available in any of the studies. Hence, it may be appropriate in view of the widespread incidence of vitamin D insufficiency, especially in older adults, for integrative oncologists to measure 25-hydroxy-vitamin D levels in patients with hematologic malignancies and supplement with a fat-soluble vitamin D3 preparation to bring the levels into sufficient or optimal range.

Green Tea

Green tea *(Camellia sinensis)* is an increasingly consumed beverage being sought after for multiple potential beneficial health effects. An inhibitor of CYP3A4 metabolism as well as a potent source of vitamin K, green tea may interact with prescribed anticancer drugs or anticoagulant therapies. However, green tea polyphenols have been shown to have antiproliferative activity against a wide variety of cell lines, including CLL,[24] multiple myeloma, and human promyelocytic leukemia HL-60. Epigallocathechin-3-gallate (EGCG) is the specific green tea polyphenol that is an antioxidant with chemopreventive and chemotherapeutic actions. Present in situ in the beverage, EGCG has also been prepared as green tea extract (GTE) supplements and even more concentrated EGCG capsules that patients can purchase in health food and supplement emporiums. The publication of the CLL data has led to increased use of EGCG in patients with low-grade lymphomas. A phase I study in patients with asymptomatic stage 0 to II CLL demonstrated that the Polyphenon E preparation use was well tolerated in 33 participants and that the majority of participants had decreased total lymphocyte counts, lymphadenopathy, or both. Of note, when taken on an empty stomach, GTE preparations have been associated with a risk of hepatotoxicity. The question of whether health benefits against hematologic malignancies can be achieved by simply drinking an as yet undetermined quantity of the beverage or higher dose preparations such as GTE or EGCG is not known.

Patients with multiple myeloma are now frequently advised by their oncologists not to consume green tea at all because of its potential to negate the treatment effects of bortezomib, found in mouse studies.

Other commonly used OTC products include turmeric, melatonin, medicinal mushrooms, and Chinese herbs. Studies are being conducted regarding their efficacy and safety.

Antioxidants

Antioxidants (e.g., beta-carotene; lycopene; vitamins C, E, and A) are substances that counteract free radicals and prevent them from causing tissue and organ damage. They are among the most common classes of supplements used by patients with hematologic malignancies. Their use is directed for cytotoxic effects, for synergy with conventional therapy, or to lessen the toxicity of conventional therapy. Estimates of antioxidant use by patients with cancer have varied considerably, with rates ranging from 13% to 87% depending on the survey, the type of disease studied, and a variety of other individual

and demographic factors.[25] Specific prevalence data on the use of antioxidants among patients with only hematologic malignancies has generally not been reported in the surveys.

Evidence supporting the potential role of antioxidants in preventing and treating disease include preclinical studies. These studies have correlated oxidative stress and an antioxidant-depleted diet with the development of diseases, including cancer. Increased consumption of green tea (which contains the anticarcinogenic agent, EGCG) has been associated with a reduced incidence of leukemia. In addition, decreases in antioxidant enzymes or the micronutrients, thiol, vitamin E, vitamin C, beta-carotene, or zinc and increases in the production of reactive oxygen species have been reported in leukemia patients. In one study in children with ALL, higher levels of oxidative stress at diagnosis were associated with a poor prognosis.

In another prospective observational study conducted among children with ALL, low plasma[26] and dietary antioxidant[27] levels directly correlated with treatment-related toxicity. These types of data have led many patients with hematologic malignancies to take antioxidant supplements primarily in conjunction with conventional cancer treatment.

Much of the controversy surrounding antioxidants and cancer therapy has arisen because radiation therapy and certain classes of chemotherapy agents exert some of their anticancer effects through the generation of reactive oxygen species or free radicals. Some of these agents include the anthracyclines (e.g., doxorubicin), platinum-containing complexes (e.g., cisplatin and carboplatin), and alkylating agents (e.g., cyclophosphamide and ifosfamide). The theoretical concern is that antioxidants might somehow interfere with or counteract the activities of these anticancer agents. However, to date, preclinical experiments and clinical studies have not definitively shown impact on treatment outcome.[28] Of particular note, an observational cohort study from the Fred Hutchinson Cancer Research Center in Seattle evaluating the prevalence of supplement use in persons before receiving hematopoietic stem cell transplant and the association of select supplements with outcomes found that pretransplant intake of vitamin C (≥500 mg/day) or vitamin E (≥400 IU/day) was associated with increased risk of relapse or mortality.[29]

Recent studies have shown interactions of antioxidant supplements with the proteasome inhibitor bortezomib. Vitamin C, at orally achievable concentrations (equivalent to 1 g/day, a dose frequently used by patients), inhibited the in vitro multiple myeloma cell cytotoxicity of bortezomib and blocked its inhibitory effect on 20S proteasome activity. In addition, green tee polyphenols and dietary supplements carrying hydroxyl groups, including flavonoid compounds such as quercetin, bind and inhibit the activity of bortezomib on malignant B cells and multiple myeloma cells in vitro, although by mechanisms independent of their antioxidant activity. Taken together, these studies suggest that antioxidant supplements should be avoided in patients taking bortezomib and other boronic acid proteasome inhibitor therapy.

The precise role of antioxidant supplementation in the patients with hematologic malignancies remains to be determined. Studies adequately evaluating the impact of supplementation on toxicity and disease free survival have not yet adequately demonstrated that the benefits of supplementation clearly outweigh the risks; therefore, the possibility of harm must be strongly considered. Recommendations for clinical practice at the present time include the following:

- Patients should be advised to avoid dietary antioxidant supplements above the basic nutritional requirements during radiation therapy and stem cell transplantation.
- Patients should avoid dietary antioxidant supplements while receiving bortezomib and other boronic acid proteasome inhibitor therapy. Counseling patients to avoid supplementation while receiving chemotherapy associated with high oxidative stress (anthracyclines, alkylating agents, platinum-containing agents, topoisomerase I and II inhibitors) is encouraged.
- Use of antioxidant supplements while receiving chemotherapy associated with low oxidative stress (purine or pyrimidine analogues, antimetabolites, monoclonal antibodies, vinca alkaloids, taxanes, and corticosteroids) is less likely to be associated with interactions. Caution should be taken with other agents (e.g., antiangiogenic agents, tyrosine kinase inhibitors) for which there is insufficient information.

Recommendations for Patients

"All patients with hematological problems should be asked specifically about their use of complementary and alternative therapies."

"All patients with hematological problems should receive guidance about the advantages and limitations of complementary therapies in an open, evidence based, and patient-centered manner by a qualified professional."

CHAPTER 159

HEMATOLOGIC MANIFESTATIONS OF HIV/AIDS

Howard A. Liebman and Anil Tulpule

Human immunodeficiency virus type 1 (HIV-1) is the pathogenic infectious agent responsible for the development of acquired immunodeficiency syndrome (AIDS). Chronic HIV infection leads to progressive immunodeficiency and immune dysregulation, resulting in an increased risk for opportunistic infections, increased incidence of certain malignancies, autoimmune disorders, and varied organ system dysfunction. Although nearly every organ system can be affected by HIV infection, hematologic manifestations involving the bone marrow and peripheral blood occur in all patients in the course of the disease. This chapter will provide a general overview of the epidemiology of AIDS, HIV virology and immunopathogenesis, and a more comprehensive review of the hematologic manifestations of HIV infection.

DEFINITION AND EPIDEMIOLOGY OF HIV INFECTION

Although the original definition of AIDS was based upon clinical symptoms and signs alone, knowledge of the viral pathogenesis has lead to a series of revised case definitions by the U.S. Public Health Service and Centers for Disease Control and Prevention (CDC). The present case definition for HIV-1 infection divides the disease into three stages as defined by $CD4^+$ lymphocyte counts and the presence of AIDS-defining conditions (Tables 159-1 and 159-2). A diagnosis of AIDS can be made by recognition of well-characterized clinical symptoms and signs (see Table 159-2) with evidence of HIV infection (clinical AIDS). HIV infection in an individual with a blood CD4 lymphocyte count of less than 0.2×10^9/L classifies the patient as having "immunologic AIDS." With the advent of routine testing for HIV infection in developed countries, a significant proportion of individuals with HIV infection who are receiving highly active antiretroviral therapy (HAART) have little or no clinical manifestations of viral infections and can maintain near-normal immunologic function. However, many of the same individuals suffer from HAART-related toxicities. The World Health Organization (WHO) originally used an alternate case definition because of the limited availability for serologic, virologic, and immunologic testing of patients in resource-poor countries but after 2007 required serologic confirmation of HIV-1 infection. Therefore the early estimates of HIV-related disease worldwide were limited by this more clinically based definition.

The CDC estimates the 2008 prevalence of HIV infection in the United States at 1,178,350 Americans with a 2009 incidence of 48,000 new infections. WHO has estimated that there were 2.7 million new HIV infections in 2009 with an estimated prevalence worldwide of 38 to 45 million people infected by HIV. However, WHO estimates a 16% decline in new infections worldwide since the year 2000; with a stable rate of new infections in Africa and Asia, but an increased incidence of new infections in Eastern Europe and central Asia. Vertical transmission from mother to infant continues in Africa and areas in Asia because of a lack of antiviral medications.

A second, but molecularly distinct HIV, human immunodeficiency virus type 2 (HIV-2), is endemic to regions of West Africa. HIV-2 and the simian immunodeficiency virus of sooty mangabeys are essentially identical, confirming its simian origin that subsequently crossed over into man. Less is known about the epidemiology of HIV-2, but infection appears to result in a less virulent clinical course than HIV-1 infection. Despite being structurally closely related to HIV-1, infection with HIV-2 does not provide protection against HIV-1 infection, and coinfection is frequent in sex workers in West Africa.

TRANSMISSION OF HIV-1

HIV may be transmitted by sexual contact with an infected individual, use of a contaminated needle in parenteral drug use, exposure to infected blood products, or prenatal transmission from infected mother to her infant.

HIV-1 has been recovered both from semen of HIV-infected men and from cervical and vaginal secretions of HIV-infected women. Virus can be detected in seminal fluid during the first 4 weeks of infection. Several factors are associated with increased viral content of seminal fluid, including advanced symptomatic HIV infection, higher plasma viral loads, CD4 lymphocyte counts less than 0.2×10^9/L, and the presence of leukocytes in the seminal fluid. Factors that influence the levels of HIV-1 in female vaginal secretions include advanced HIV stage of HIV infection, menstruation, concomitant vaginal infection, ulcerative and nonulcerative sexually transmitted diseases and a high HIV-1 viral plasma load. Prevention and treatment of sexually transmitted disease has been associated with a decrease in HIV-1 transmission.

The risk for HIV infection with transfusion of a single unit of infected blood is estimated at greater than 90%. The use of coagulation factor concentrate prepared before routine screening of blood products for HIV-1 in the United States resulted in an unfortunately high incidence of HIV infection in patients with congenital bleeding disorders. With active blood product screening and inactivation protocols used in the preparation of coagulation factor concentrate, HIV transmission has been essentially eliminated. With screening of all blood units in the United States, receipt of a unit of screened blood is associated with an estimated risk for transmission of approximately 1 in 500,000.

HIV may be transmitted to a fetus or infants from the mother in utero, at the time of delivery, or postpartum through breastfeeding. The risk is greatest when the mother has advanced HIV disease, higher HIV viral load in the plasma, and active injection drug use. At the time of delivery, active chorioamnionitis, premature rupture of amniotic membranes (>4 hours), and vaginal delivery, as opposed to elective cesarean section, have been associated with an increased risk for maternal-infant transmission. Prematurity, low gestational age, and breastfeeding have been reported as risk factors for HIV transmission. The use of antiretroviral agents in pregnancy, during delivery, and during the first 6 weeks of life has resulted in a significant reduction in transmission from an estimated 25% to 8% with zidovudine alone and even greater benefit with the use of HAART. To date, except for the use of efavirenz, there is no evidence to suggest an increased risk for congenital birth defects with the use of antiretroviral agents for this indication. The use of antiretroviral therapy during pregnancy has resulted in a nearly 50% reduction in the number of children with perinatal-acquired HIV infection.

Table 159-1 Surveillance Case Definition for HIV Infection in Adults and Adolescents (Age Over 13 Years)

Stage	Laboratory Evidence	Clinical Evidence
Stage1	Laboratory confirmation of HIV infection and $CD4^+$ T-lymphocyte count of ≥500 cells/μL or $CD4^+$ T-lymphocyte percentage of ≥29*	No AIDS-defining condition (see Table 159-2)
Stage 2	Laboratory confirmation of HIV infection and $CD4^+$ T-lymphocyte count of 200-499 cells/μL or $CD4^+$ T-lymphocyte percentage of 14-28*	No AIDS-defining condition (see Table 159-2)
Stage 3	Laboratory confirmation of HIV infection and $CD4^+$ T-lymphocyte count of <200 cells/μL or $CD4^+$ T-lymphocyte percentage of <14*	Documentation of an AIDS-defining condition with laboratory confirmation of HIV infection (see Table 159-2)
Stage unknown	Laboratory confirmation of HIV infection and no information on $CD4^+$ T-lymphocyte count or percentage	No information on presence of an AIDS-defining condition

AIDS, Acquired immunodeficiency syndrome; *HIV,* human immunodeficiency virus.
*The $CD4^+$ T-lymphocyte percentage is the percentage of the total lymphocyte count.

Table 159-2 Surveillance Definitions of AIDS-Defining Conditions

Opportunistic infections
Pneumocystis jiroveci (carinii)
Mycobacterium avium complex
Mycobacterium tuberculosis
Toxoplasmosis
Candidiasis: esophageal and systemic
Histoplasmosis
Cryptococcosis
Cryptosporidiosis and isosporiasis
Leishmaniasis
Cytomegalovirus disease
Recurrent bacterial infections (≥2 episodes/yr)
Lymphomas
Kaposi sarcoma
Cervical cancer
AIDS dementia syndrome
Wasting syndrome

AIDS, Acquired immunodeficiency syndrome.

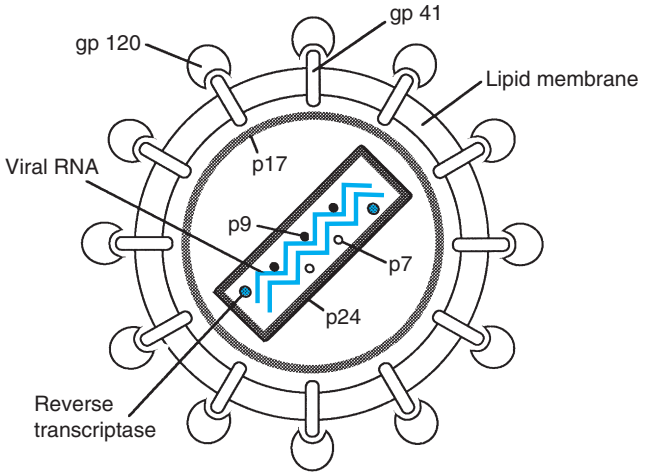

Figure 159-1 STRUCTURE OF THE HIV VIRION. Two coding strands of genomic ribonucleic acid (RNA) are packaged in the nucleoid core with p7, p9, and p24 proteins and reverse transcriptase. The core is surrounded by the p17 matrix protein lining the inner surface of the envelope. The envelope consists of a lipid bilayer derived from the infected cell and glycoprotein spikes that consist of the outer gp120 molecule, which contains the binding site for CD4, and gp41, which anchors the glycoprotein complex to the envelope and mediates fusion of the viral membrane with the cell membrane during viral penetration. *HIV,* Human immunodeficiency virus.

Transmission can also occur by the sharing of needles and syringes between injection drug users. The use of cocaine and other noninjection drugs can be associated with an increased risk for HIV infection in that their use is frequently associated with high-risk sexual behaviors. Needlestick exposures can also result in transmission of HIV from infected patients to health care workers. The risk for transmission is increased if the patient who is the source of the contaminated needle has more advanced disease with a high plasma viral load, if the needle injury is deep, if there is visible blood on the needle, or if the injury directly enters a vein or artery. The estimated risk for acquiring HIV is approximately 0.3% per needle injury exposure if the source of the blood is a patient with advanced HIV infection (stage 3 AIDS). The use of a 4-week course of antiretroviral therapy as postexposure prophylaxis has been shown to significantly reduce the risk for transmission. Prophylaxis using drug regimens recommended by the CDC should be initiated within 72 hours of exposure and continued for a duration that is based upon the stage of the patient who was the source of the exposure and the type of exposure.

ETIOLOGY AND PATHOGENSIS

Human Immunodeficiency Virus Type 1

HIV-1 is a member of the primate Lentivirinae subfamily of retroviruses. Retroviruses are ribonucleic acid (RNA) viruses that induce a chronic cellular infection by converting their RNA genome into a deoxyribonucleic acid (DNA) provirus that is integrated into the genome of the host cell. The genome of the virus contains three major genes necessary for viral replication and cellular invasion. The env gene codes for a 160-kD precursor protein that is processed into a 120-kD surface glycoprotein (gp) noncovalently linked to a 41-kD transmembrane protein. The gp120-gp41 complex is necessary for virus binding to CD4 and CCR5 on the cell membrane and fusion of the viral envelope with the cell membrane, allowing for the release of the viral genome into the host cell. The gag gene codes for the four viral structural core proteins. These proteins form the nucleocapsid for the viral genome and assist in assembly of the replicating virus before viral release from the cell membrane. The pol gene codes for three functional enzymes; a reverse transcriptase necessary for formation of the proviral double-strand DNA, an integrase necessary for stable integration of the proviral DNA into the host cellular DNA, and viral protease necessary for processing viral membrane and core proteins (Figs. 159-1 and 159-2).

In addition to these three essential genes, the 9-kD genome of HIV-1 contains six additional genes (vif, vpu, vpr, tat, ref, nef) necessary for the regulation of viral gene expression, cellular latency, and each gene product playing an important role in the life cycle of HIV.

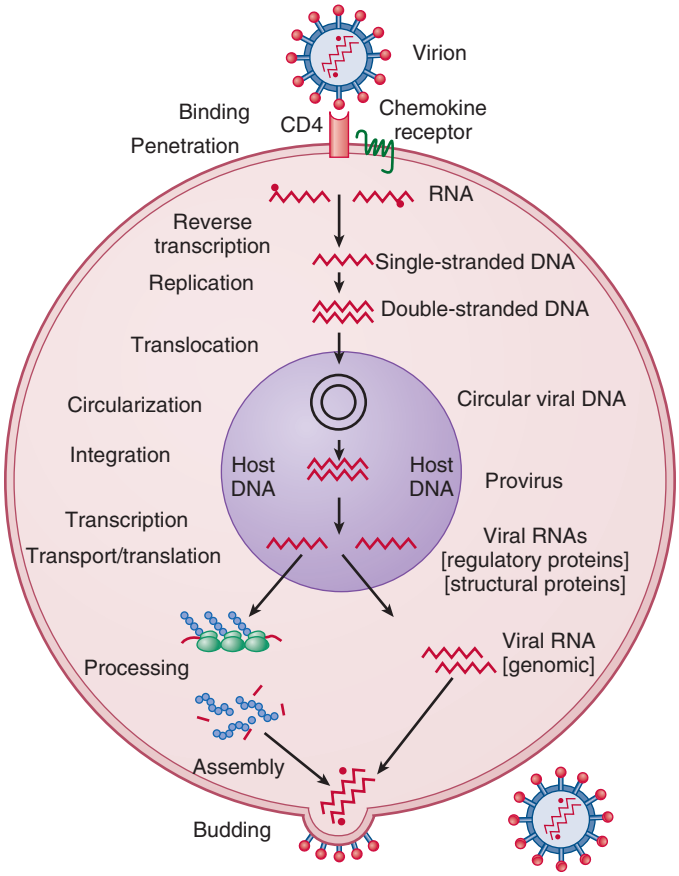

Figure 159-2 HIV LIFE CYCLE. Binding of the virion to the cell surface is mediated by a specific interaction of the gp120 envelope glycoprotein with cellular CD4 and members of the chemokine receptor family of proteins (CCR5 or CXCR4). Penetration occurs as the viral membrane fuses with the cellular membrane in a process that requires the gp41 transmembrane protein. The viral capsid is uncoated, and viral genomic ribonucleic acid (RNA) is reverse transcribed and duplicated by the viral reverse transcriptase to produce a double-stranded copy of viral deoxyribonucleic acid (DNA). The viral DNA is transported to the nucleus, where it integrates into the host chromosomes. After appropriate activating signals, the provirus is transcribed by cellular RNA polymerase and transported to the cytoplasm. Proteins are translated and processed through biochemical steps that, depending on the protein, involve glycosylation (gp120 and gp41), cleavage (envelope proteins, gag, pol), myristoylation (p17), and phosphorylation (rev, nef). Packaging of genomic RNA with viral proteins occurs as envelope glycoproteins are inserted into the cell membrane and new virion subsequently buds outward from the plasma membrane. Viral protease continues protein processing to completion during viral budding. *HIV,* Human immunodeficiency virus.

Life Cycle of HIV-1

Cellular infection begins with engagement of HIV-1 gp120 binding to CD4 surface membrane protein, resulting in a conformational change in gp120 allowing for further high-affinity binding to chemokine CCR5 receptor (see Fig. 159-2). Thymic helper-inducer (CD4) lymphocytes, macrophage-monocytes, Langerhans cells, follicular dendritic cells, megakaryocytes, and thymic cells express both CD4 and CCR5 receptors molecules and are susceptible to HIV-1 infection. Rare individuals who are homozygotes for the delta32 deletion in CCR5 are highly resistant to HIV-1 infection. The structural diversity of gp120 viral receptor has resulted in HIV-1 strains with selective or restricted patterns of infection with strains that readily infect monocytes, whereas others are tropic for CD4 lymphocytes. Some $CD4^+$-tropic strains may also use the CXCR4 chemokine receptor in addition to the CCR5 receptor.

Upon binding to the CD4 and CCR5 receptors, the viral transmembrane gp41 mediates fusion with the host cell membrane. The internalized viral nucleocapsid dissociates after binding to cellular cyclophilin, releasing the diploid viral RNA genome that is associated with the viral reverse transcriptase. Reverse transcription proceeds to synthesis of a single-strain complementary DNA (cDNA), followed by degradation of the viral RNA by ribonuclease H activity of p66. The reverse transcriptase then acts as a DNA polymerase, forming a double-stranded DNA provirus. The reverse transcriptase of HIV has a significant rate of base substitution errors estimated as high as 1 in 1700 to 1 in 2000 nucleoside bases, resulting in an average of 5 to 10 nucleoside mutations for each replication cycle. This explains the high degree of genomic diversity observed between HIV-1 viral isolates.

A linear form of the provirus is integrated into the host DNA by the viral integrase. In kinetic studies of HIV-1 infection, viral DNA is present in the cytoplasm within 2 to 3 hours of infection, whereas viral nuclear DNA has been detected by 24 hours. The gene product of vpr assists in transport of the proviral DNA into the nucleus for subsequent integration. After integration of the viral genome, the HIV-1 infected cell may develop either a latent or persistent form of infection.

HIV-1 does not replicate readily in resting lymphocytes and macrophages. Cellular transactivation, by NF-κB, for example, can enhance proviral transcription. HIV-1 proviral transcription leads to the expression of regulatory proteins tat, rev, and nef. Tat is a protein essential for HIV replication, and in conjunction the cellular proteins TAK (Tat-associated kinase) and Cyc T (cyclin T) promote viral RNA elongation resulting in a 1000-fold increase in HIV-1 expression. Rev is a viral protein that is also essential to replication by regulating nuclear export of unspliced viral RNA. Nef and vpu proteins modulate the downregulation of cellular CD4.

The structural proteins of the gag, pol, and env genes are expressed as precursor proteins and subsequently cleaved by viral protease, yielding mature viral proteins. This final step in protein processing is essential for the assembly of mature infectious virus. For this reason, inhibition of the viral protease has proven a fruitful target for ART. The products of the env gene, gp120, and gp 41, are transported to the cell membrane and the assembled ribonucleoprotein core moved from the cytoplasm to the membrane surface for subsequent budding. The efficient packaging of the viral RNA is dependent upon packaging signals in the gag region of the viral RNA. Final budding is dependent upon the product of the vpu gene, which also assists in transport of env products to the cell membrane and association with the ribonucleoprotein core.

Pathogenesis of HIV Infection

HIV infection results in progressive immunodeficiency and immune dysregulation. By progressive depletion of helper CD4 thymic lymphocytes there is decreased response to soluble antigens, decreased helper response to immunoglobulin synthesis, and impaired delayed hypersensitivity. Decreased interferon-γ production leads to decreased cytoplasmic killing of intracellular organisms. There is also defective natural killer (NK) function and decreased T lymphocyte–mediated cytotoxicity of viral infected cells. An imbalance of CD4, CD25, $Foxp2^+$ regulatory cells, and CD4/interleukin (IL)-17 lymphocytes may result in the expression of autoreactive T and B lymphocytes, accounting for the increased incidence of autoimmune disorders associated with HIV infection and defective CD8 responses against HIV-infected lymphocytes. Viral expression in activated CD4 lymphocytes results in rapid cell death, whereas infection of macrophages, dendritic cells, and nonreplicating CD4 lymphocytes accounts for a persistent and long-lived reservoir of HIV-1 infected cells. High-level viral replication and budding associated with potent immunostimulation from acute and chronic infections may contribute to accelerated lymphocyte cytotoxicity.

In addition to the direct cytopathic effect of viral replication in CD4 lymphocytes, formation of syncytial multinucleated giant cells

by fusion of infected CD4 lymphocytes expressing gp120 on their membrane with uninfected $CD4^+$ lymphocytes is another mechanism for CD4 depletion. Viral strains capable of forming such syncytia in vitro appear to be associated with a more aggressive clinical course. The host immunologic response against HIV-infected lymphocytes by cytotoxic T lymphocytes and antibody-mediated cellular cytotoxicity may also contribute to CD4 lymphocyte loss in HIV disease. Some CD4 lymphocytes may also be destroyed by an "innocent-bystander" mechanism secondary to the binding of free gp120 to their surface CD4 protein. In vitro studies have found that binding of the gp120 with anti-gp120 antibodies to the CD4 receptor can induce in the lymphocyte programmed cell death or apoptosis. Defective production of immune-stimulatory cytokines (IL-2) and expression of inhibitors of T-lymphocyte proliferation such as transforming growth factor-β (TGFβ) may also contribute to the progressive loss of CD4 lymphocytes.

The development of progressive CD4 lymphocyte depletion and its resulting immunodeficiency is closely linked to the degree of viral production. The level of plasma HIV-1 viral RNA, in addition to the CD4 lymphocyte count, is a major prognostic indicator of disease progression. The advent of HAART capable of marked suppression of viral replication has radically changed the natural history of HIV infection. Efficient viral suppression with reduction in blood and tissue viral reservoirs has resulted in prolonged immunologic reconstitution characterized by increased CD4 lymphocyte numbers, reduced opportunistic infections, and prolonged survival. However, significant immune defects do persist, and complete immunologic reconstitution with normal immune regulation does not occur.

There appears to be a more selective effect of HIV cytotoxicity on memory CD4 lymphocytes and Th1 lymphocyte subsets. This contributes to a profound imbalance in host immune responses with resulting B-lymphocyte dysregulation leading to polyclonal hypergammaglobulinemia and defective cellular immune responses against malignant or viral infected cells (including HIV-infected lymphocytes). Infection of monocytes, macrophages, and dendritic cells not only provide a long-lived reservoir for HIV, but further contribute to the immunologic dysfunction because of their role in antigen presentation and cytokine production.

CLINICAL COURSE OF HIV-1 INFECTION

Serial assessment of HIV-1 RNA in plasma and $CD4^+$ lymphocytes has proven to be a reliable means for following HIV-1 infection and predicting the course of disease in individual patients. The use of HAART has significantly changed the natural history of HIV disease. With active surveillance programs that can find HIV-1 infected individuals before the development of symptomatic disease, the early use of HAART based upon U.S. Public Health Service guidelines has resulted in significant decreases in the incidence of HIV-defining opportunistic infections. Based upon laboratory markers of disease progression, guidelines from the U.S. Public Health Service recommend the initiation of HAART in all symptomatic HIV-1-infected patients and asymptomatic patients with $CD4^+$ lymphocyte counts less than 0.35×10^9/L or when plasma HIV viral load reaches 55×10^6 copies/L or greater.

Three general stages of HIV infection have been characterized: an acute retroviral syndrome, an asymptomatic stage, and a period of symptomatic conditions that may or may not fulfill criteria for classification as symptomatic AIDS. The acute retroviral syndrome occurs in approximately 50% to 80% percent of infected individuals. The onset of symptoms occurs 1 to 3 weeks (range, 5 days to 3 months) after primary infection. Symptoms last from 1 to 2 weeks and can include significant fatigue, headache, malaise, fever as high as 40° C, sore throat, and myalgias. A morbilliform rash can be observed in 40% to 50% of patients with generalized lymphadenopathy occurring toward the end of the acute illness. Symptoms are similar to those observed in other viral syndromes such as mononucleosis. Laboratory findings may include lymphocytosis, occasional neutropenia, and mild thrombocytopenia. Most symptoms subside within a month. However, lymphadenopathy may persist in over 50% of patients and is termed the persistent generalized lymphadenopathy syndrome of HIV infection. Patients may be serologically negative during the acute retroviral syndrome, and if there is high clinical suspicion, patients should be tested by reverse-transcriptase polymerase chain reaction (RT-PCR) for the presence of plasma virus RNA, which is frequently present in high levels.

With resolution of the acute retroviral syndrome, patients may enter a phase of asymptomatic infection with lower levels of viral replication as determined by their plasma viral load with serologic evidence of infection. Without antiretroviral therapy, this phase may persist for nearly a decade. Progression can be variable and is determined by a variety of viral, immunologic, and host factors. Coinfections with other viruses such a hepatitis B and C, cytomegalovirus (CMV), Epstein-Barr virus (EBV), and herpesviruses can impose additional immunologic stress, leading to accelerated progression of disease and additional AIDS-defining clinical conditions. Infection with human herpesvirus 8 (HHV-8) is associated with the well-characterized AIDS-defining complications of Kaposi sarcoma, primary effusion lymphoma, and multicentric Castleman disease. EBV infection may contribute to the high incidence of lymphoma, including central nervous system lymphomas, observed in severely immunosuppressed HIV patients.

A distinct subset of HIV-1-infected patients has a significantly slower rate of HIV disease progression and maintains good immunologic function for extended periods without antiretroviral therapy. These individuals, termed *long-term nonprogressors,* are a population of significant clinical and research interest. They include patients who are heterozygous for the delta 32 deletion in the CCR5 chemokine coreceptors for HIV infection. This mutation is estimated to occur in 15% of whites. Patients with human leukocyte antigens HLA-B27 and HLA-B57 also appear to have better control of HIV viral replication and slower disease progression. This may be due to an inability of these patients' T regulatory lymphocytes to suppress CD8 cytotoxic–lymphocyte HIV-specific responses.

In the absence of antiretroviral therapy, HIV-infected patients develop progressive immunodeficiency with the development of opportunistic infections, central and peripheral neurologic symptoms, HIV-associated malignancies, fatigue, weight loss, and a general wasting syndrome (see Table 159-2).

HEMATOLOGIC AND BONE MARROW ABNORMALITIES IN HIV-1 INFECTION

The hallmark of HIV infection is the $CD4^+$ lymphopenia. However, during the course of the disease about 70% to 80% of patients with HIV/AIDS will develop anemia, 50% will develop neutropenia, and 40% will develop thrombocytopenia. The presence of cytopenias in addition to the $CD4^+$ T lymphopenia of HIV disease has long suggested that the suppressive effects of HIV on the hematopoietic compartment are far more broadly based than just a select subset of T cells. A number of studies have assessed the bone marrow microenvironment, the cytokine milieu, and the number and the function of primitive hematopoietic elements in HIV disease. A low fraction of progenitor cells can be infected ex vivo by HIV under some conditions. The growth of these few cells infected by HIV may not be impaired as a result of infection. However, in vivo infection of progenitor cells rarely if ever occurs. Progenitor populations such as those yielding megakaryocytes or monocytes can be infected.

HIV infection leads to hematopoietic inhibition in vivo by depleting myeloid and erythroid colony-forming precursor activity. This activity may be due to an indirect mechanism rather than direct infection of $CD34^+$ cells. The presence of messenger RNA for and cell surface expression of HIV receptor CD4 and the chemokine receptors CXCR4 and CCR5 have been demonstrated in fractionated cells representing multiple stages of hematopoietic development. Productive infection by HIV via these receptors is observed with the notable exception of stem cells, in which case the presence of CD4, CXCR4, and CCR5 is insufficient for infection.[1] Although direct

infection of stem cells does not occur, alterations in stem cell number and function have been documented. HIV replication in the bone marrow microenvironment is believed to be the essential component causing decreased hematopoietic cell production in HIV infection.[2] The exact mechanism by which the microenvironment induces these alterations is unknown. Mononuclear macrophage cells can develop productive HIV infection, and the resultant aberrant release of cytokines, such as TGFβ, tumor necrosis factor-α (TNF-α), and IL-1, can contribute to the suppression of hematopoiesis. TNF-α is a potent mediator of inflammation and host response to infectious diseases, with pleiotropic effects such as tissue damage, caloric wasting, and impairment of hematopoiesis. It has been observed that HIV suppresses hematopoiesis through induction of TNF-α. TNF-binding protein has been shown to reverse in vitro hematopoietic defects.[3] The relationship of virus replication to inducing the hematopoietic defects is most readily apparent in the clinical changes seen when patients initiate potent antiretroviral therapy. When patients begin HAART therapy, an increase in white blood cells, polymorphonuclear neutrophils, and platelets in addition to an increase in $CD4^+$ T cells occurs as plasma HIV RNA levels decline.[4] T cell–kinetics studies have demonstrated a markedly shortened half-life of peripheral blood T cells from approximately 82 days to 23 days. Initiation of antiretroviral therapy does not improve lymphocyte half-life. The increase in T cell numbers in the peripheral blood of patients treated with HAART appears to be a result of improved production, which in turn may be due to one of several mechanisms: expansion or redistribution of existing subsets of cells or de novo production of T cells from the thymus. The increase in T cells following initiation of HAART is biphasic. In the interval immediately following the start of therapy, there is a prompt increase in both $CD4^+$ and $CD8^+$ cells that is composed predominantly of cells of a memory phenotype ($CD45RO^+$ or $CD45RA^+$ $CD62L^-$). This increase is slightly different for $CD4^+$ cells, which increase more briskly (0.027/day) and plateau at approximately 3 weeks compared with $CD8^+$ cells (increase of 0.008/day), which plateau at 8 weeks.[5] This increase is thought to be due largely to redistribution from peripheral tissues, perhaps related to a changing level of activation of the cells with declining viral antigen stimulation. This initial increase in circulating cell numbers does not achieve normal blood levels of lymphocytes. The secondary, much slower phase of T-cell increase tends to be sustained for months to years with a greater contribution of cells with a naive phenotype ($CD45RA^+$ $CD62L^+$). The naive population rises along with cells bearing the T cell–receptor excision circle, an indicator of recent T cell–receptor rearrangement that accompanies early T-cell differentiation. It is this population that is generally regarded as thymus dependent and that is capable of truly expanding the immune repertoire. In addition, in vivo models have further defined that T-cell generation from precursor populations both endogenous and exogenous to the thymus accompanies control of viremia.

Evaluation of Cytopenias in HIV-Infected Individuals

The evaluation of cytopenias in patients infected with HIV requires a review of the complete blood cell count and thorough examination of the peripheral blood smear (see box on Peripheral Blood Smear and Bone Marrow Morphology in HIV/AIDS). Although there is a gradual fall in CD4-positive lymphocytes during the asymptomatic phase of HIV infection, a mild lymphocytosis may at times be seen because of an increase in CD8-positive lymphocytes. Atypical or activated lymphocytes may frequently be seen. Lymphopenia is present in the advanced stage of disease. Anemia, when present, is usually normocytic and normochromic. It can be at times macrocytic, either due to the effect of certain antiretroviral drugs such as zidovudine or stavudine or seen in patients with advanced HIV disease (Fig. 159-3). Occasionally red blood cell (RBC) anisocytosis, poikilocytosis, and rouleaux can be seen in patients with untreated advanced HIV disease. Also, hypogranular neutrophils and Pelger-Huët forms may rarely be present in patients with advanced HIV disease. However, in comparison to patients with myelodysplastic syndrome (MDS), agranular neutrophils and neutrophils with the acquired Pelger-Huët anomaly are not a predominant feature in patients with HIV infection. Thrombocytopenia is associated with normal-sized platelets, except occasional large platelets may be seen when there is immune-mediated destruction of platelets with preserved marrow function.

The bone marrow in patients with HIV can be hypercellular, normocellular, or hypocellular (see Fig. 159-3). In a majority of cases the normal bone marrow architecture is often disturbed with dysplastic changes similar to what is seen in MDS.[6] Associated stromal changes include edema, gelatinous transformation and lymphoid infiltrates, and granuloma with increased reticulin fibers. Dense collagen fibrosis, however, is not a feature of the HIV bone marrow.

There are some important features distinguishing the morphology of the bone marrow of an HIV-infected individual from that of patients with MDS. Dyserythropoiesis is usually less severe in HIV disease than observed in MDS and occurs predominantly in patients treated with HAART. Megaloblastic changes are usually associated with zidovudine and stavudine therapy. In contrast to MDS, in which erythropoiesis maybe hyperplastic, the myeloid/erythroid ratio in HIV is usually normal, and there may even be neutrophilic and megakaryocytic hyperplasia. An increase in blasts can be seen in MDS, but never in bone marrow in HIV-infected patients, unless they have an associated leukemia. In contrast to MDS, the bone marrow in HIV patients often shows eosinophilia, lymphohistiocytic infiltrates, and reactive plasmacytosis.

Although a bone marrow examination is not routinely required to evaluate isolated anemia, thrombocytopenia, or neutropenia in patients with HIV infection, a bone marrow examination can be useful in the evaluation of unexplained fever and in patients with pancytopenia suspected of having marrow infiltration with an infectious agent or malignancy. Granulomas are observed in approximately 15% of bone marrow trephines and may be due to the HIV infection

Peripheral Blood Smear and Bone Marrow Morphology in HIV/AIDS

The peripheral blood smear of a patient with HIV/AIDS might show anisocytosis, poikilocytosis, and rouleaux formation. Anemia when present is usually normocytic and normochromic. Sometimes macrocytic anemia can be seen even in the absence of zidovudine therapy. Lymphopenia is seen in advanced disease. Hypogranular neutrophils and Pelger-Huët forms are rarely present. Platelets can be normal or hypogranular. In cases of thrombocytopenia the platelets can be normal-sized or large when thrombocytopenia is due to immune destruction with preserved marrow function.

The bone marrow is usually hypercellular but can be normocellular or hypocellular. Interstitial and perivascular polyclonal plasmacytosis is usually present. HIV-associated stromal changes include edema, gelatinous transformation, and increased reticulin fibers (dense collagen fibers are not a feature of HIV). Normal bone marrow architecture is often disturbed, and dysplastic changes can be seen, including dyserythropoiesis, dysgranulopoiesis, and abnormal megakaryocytes (including clusters and bare megakaryocytic nuclei). However, the following features distinguish the bone marrow morphology in HIV from that of myelodysplastic syndrome (MDS): Dysplasia is less severe in HIV. Dyserythropoiesis occurs mainly in patients on highly active antiretroviral therapy (HAART). Megaloblastic changes are associated with zidovudine therapy. Whereas erythropoiesis is usually hyperplastic in MDS, myeloid/erythroid ratio is usually normal in HIV. Increased blasts can be seen in MDS but never in HIV. Lastly, in contrast to MDS, the basement membrane in HIV often shows eosinophilia, lymphohistiocytic infiltrates, and plasmacytosis.

AIDS, Acquired immunodeficiency syndrome; *HIV,* human immunodeficiency virus.

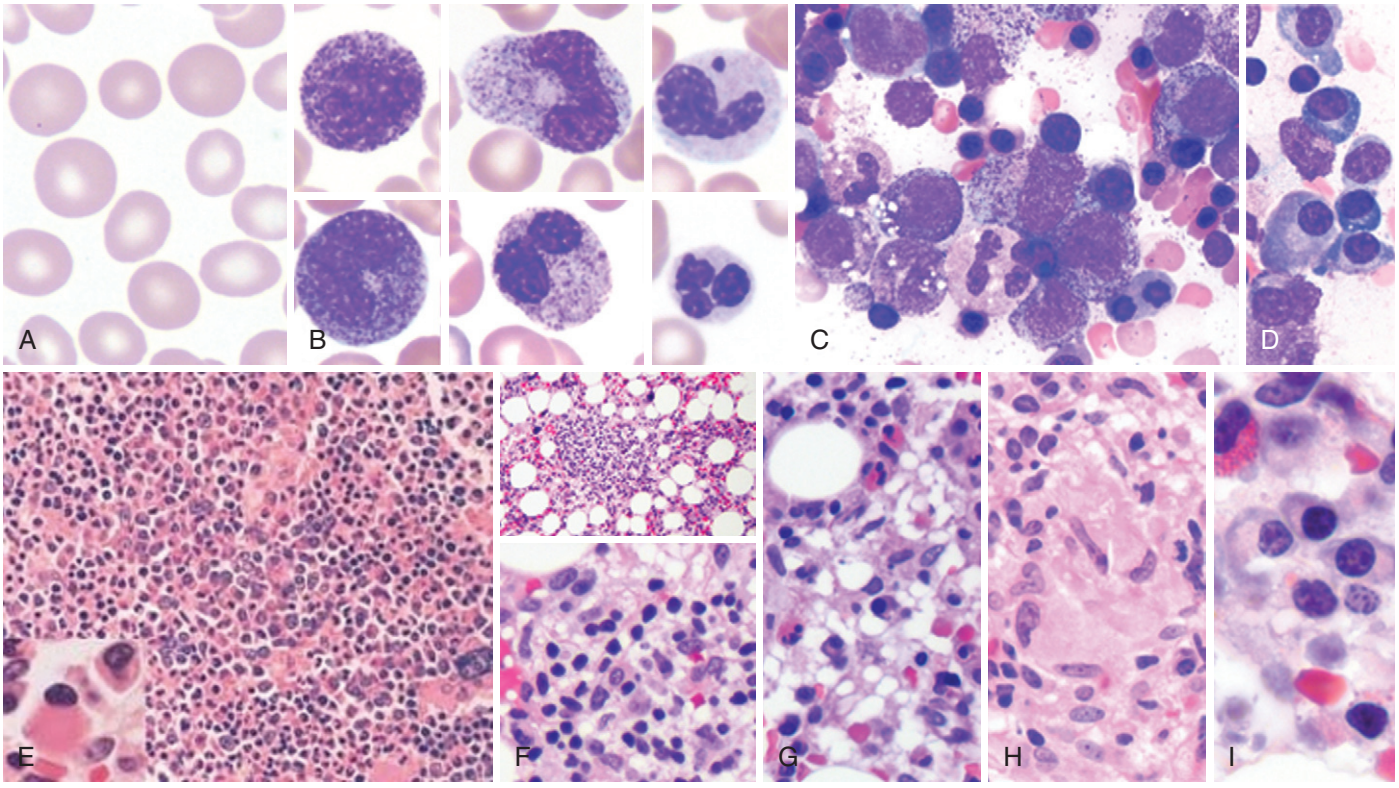

Figure 159-3 TYPICAL PERIPHERAL BLOOD AND BONE MARROW FINDINGS IN HIV. The peripheral smear not uncommonly shows anemia, which is sometimes macrocytic **(A)**, but can be normochromic and normocytic. There frequently is a neutrophilia with left shift, toxic granulation, and some mild dysplastic change in the granulocytes **(B)**. In some patients, particularly those with severe disease, some of the segmented neutrophils show cytoplasmic inclusions similar to Howell-Jolly bodies seen in red cells (**B**, *top, right cell*). These are nuclear in origin and are not microorganisms. The bone marrow can show granulocytic hyperplasia with left shift and megaloblastoid change in the myeloid and erythroid cell lines **(C)**. Typically, there is also a reactive plasmacytosis **(D)**. The biopsy specimen can be hypocellular, normocellular, or hypercellular **(E)** and commonly shows cellular atypia/dysplasia *(insert)* and atypical reactive lymphoid infiltrates **(F)**, poorly formed **(G)** or well-formed granuloma **(H),** and increased plasma cells **(I).**

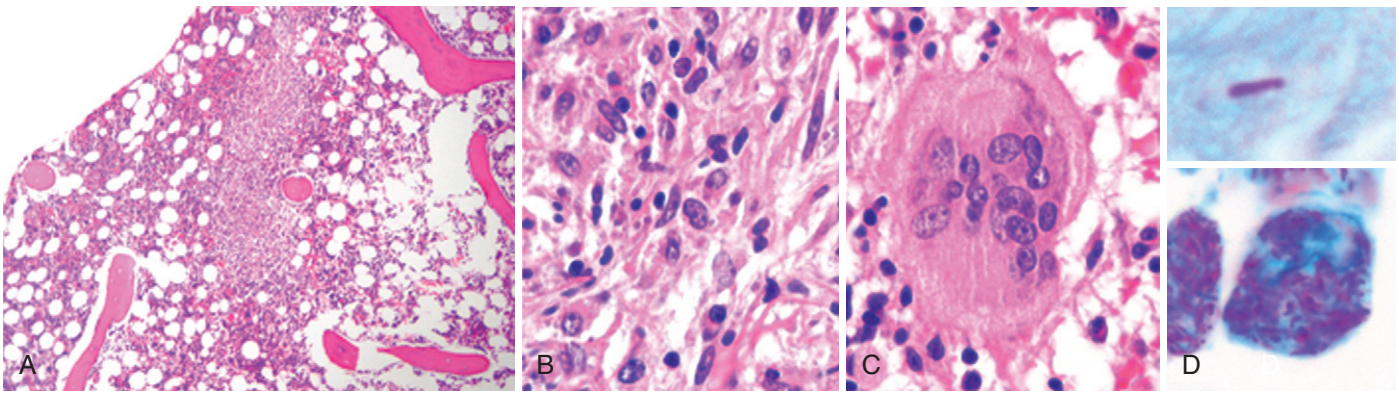

Figure 159-4 ACID-FAST ORGANISMS IN GRANULOMA. Large poorly formed granuloma in the bone marrow **(A)**, is composed of loosely aggregated histiocytes, lymphocytes, and plasma cells **(B)**, with occasional giant cells **(C)**. The acid-fast stain shows rare elongated, slightly beaded organisms, typical of *Mycobacterium tuberculosis* **(D,** *top*). In *Mycobacterium avium* complex, the organisms frequently stuff histiocytes (**D,** *bottom*).

alone, but a thorough search for mycobacterium and other infections is required. A particular effort should be made to identify bone marrow involvement with opportunistic infections, which could include mycobacterial (Fig. 159-4), fungal, protozoal, and/or viral infections.[6] Cytopenias in HIV-infected individuals may also be due to bone marrow involvement by non-Hodgkin lymphoma (Fig. 159-5), Hodgkin lymphomas (Fig. 159-6), Kaposi sarcoma, and Castleman disease.

The etiology of cytopenias in HIV/AIDS is frequently multifactorial. In addition to HIV infection, the medications often prescribed to HIV-infected patients can account for a significant proportion of cytopenias. A thorough review of the medications and supplements taken by an HIV/AIDS patient with a cytopenia is essential. Tables 159-3 and 159-4 list antiretroviral and antiinfective medications prescribed for prophylaxis/treatment of opportunistic infections and their association with hematologic toxicities.

The clinical presentation and management of individual cytopenias can be unique, and therefore the diagnosis and management of anemia, thrombocytopenia, and neutropenia in HIV/AIDS are addressed separately later. In addition, the emerging issue of thrombosis in HIV and principles of antiretroviral therapy management will also be discussed in this chapter.

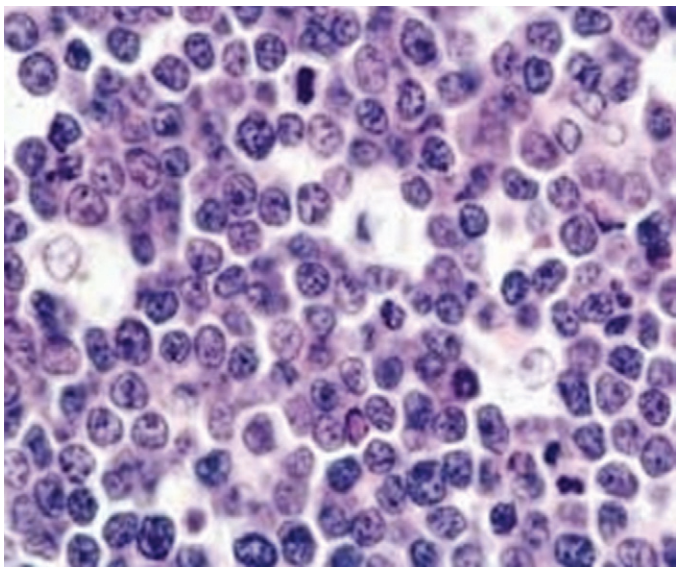

Figure 159-5 BURKITT LYMPHOMA INVOLVING THE BONE MARROW OF A PATIENT WITH ACQUIRED IMMUNODEFICIENCY SYNDROME (AIDS). *(Zhao X, Sun NC, Witt MD, et al: Changing pattern of AIDS: A bone marrow study. Am J Clin Pathol 121:393, 2004.)*

Anemia in HIV/AIDS

Anemia can occur at any stage of HIV disease but is more frequent and severe in advanced disease. Anemia in HIV disease is independently associated with an increased risk for disease progression and mortality. In general, the etiology of anemia seen in HIV infection is often multifactorial, with several mechanisms playing a role in an individual patient. Anemia could be due to decreased red blood cell (RBC) production, ineffective RBC production, or increased RBC destruction. A methodical workup of anemia in a patient with HIV should be similar to that for anemia in the HIV-negative individual.

The most common cause of anemia in HIV disease is decreased RBC production. Frequently encountered mechanisms responsible for decreased RBC production in patients with HIV include anemia of acute and chronic inflammation (chronic disease anemia), infection or infiltration of bone marrow by infectious agents such as atypical mycobacterium, tuberculosis, cytomegalovirus, and/or fungal organisms or malignancies such as lymphoma. Parvovirus B19 can cause isolated red cell aplasia in the more severely immunocompromised individuals. Medications used for treatment of HIV or other illnesses and for prophylaxis of opportunistic infections can cause anemia mostly due to decreased RBC production. The list of medications as in Tables 159-3 and 159-4 is extensive. Hence it is very important that a thorough review of all the medications is done. Nutritional deficiencies, including vitamin B_{12} and folic acid deficiency, are causes of anemia due to ineffective production.

Other causes of anemia include anemia secondary to blood loss or hemolysis. Causes of hemolysis include medications such as sulfonamides and dapsone in individuals with glucose-6-phosphate dehydrogenase (G6PD) deficiency, thrombotic thrombocytopenic purpura or hemophagocytic syndrome. Patients with advanced HIV infection (AIDS) appear to acquire gastrointestinal defects resulting in B_{12} malabsorption.

Diagnosing the cause or causes of anemia is essential to proper therapy. Treatment of anemia should be directed toward correcting the underlying cause whenever possible. The use of blood transfusion should be minimized and reserved for patients who have rapid decreases in hemoglobin levels, extremely low hemoglobin levels, or pronounced anemia-related symptoms. Antiretroviral medication combinations (highly active antiretroviral therapy [HAART]) have shown that suppression of HIV replication is associated with improvement in anemia. Erythropoietin supplementation has been shown to be beneficial in HIV-infected patients with well-established anemia and when the hemoglobin level is decreasing or has decreased slowly. The primary goal of treating anemia should be to maintain quality of life and functional status.

AIDS, Acquired immunodeficiency syndrome; *HIV,* human immunodeficiency virus.

Red Blood Cell Abnormalities and Anemia

Anemia can occur at any stage of HIV disease but is more frequent and severe in advanced disease[7] (see box on Anemia in HIV/AIDS). There is increasing evidence suggesting that anemia in HIV disease is independently associated with an increased risk for disease progression and mortality.[7,8] Anemia is associated with an increased risk for death in HIV-infected patients regardless of CD4 count, and survival is not significantly different between patients with drug-related anemia and anemia attributed to other causes.[7] Correction of anemia in HIV-infected patients has been associated with measurable improvements in quality of life[7] and increased survival.[7]

Detection and treatment of the underlying cause of the anemia should be an immediate goal, which may involve the treatment of opportunistic infections or gastrointestinal blood loss. In general, the etiology of anemia seen in HIV infection is often multifactorial, with several mechanisms playing a role in an individual patient. Diagnosing the cause or causes of anemia is essential to proper therapy.

Anemia Due to Decreased Production

The most common cause of anemia in HIV disease is decreased RBC production. Frequently encountered mechanisms responsible for decreased RBC production in patients with HIV disease are listed in Table 159-5. Examples include anemia of acute and chronic inflammation (chronic disease anemia) with a blunted production of and response to erythropoietin and cytokine suppression of bone marrow

colony-forming unit–granulocyte, erythrocyte, macrophage, megakaryocyte (CFU-GEMM). Infection or infiltration of bone marrow by infectious agents such as atypical mycobacterium, tuberculosis, cytomegalovirus, and/or fungal organisms can result in profound anemia, although most often associated with pancytopenia. Parvovirus B19 can cause isolated red cell aplasia in the more severely immunocompromised individuals. Bone marrow infiltration by HIV-associated lymphomas, in addition to anemia, can cause neutropenia and thrombocytopenia. Nutritional deficiencies, including vitamin B_{12} and folic acid deficiency, are not uncommon. Other causes of anemia, including anemia secondary to blood loss or hemolysis as seen in the non–HIV patient population, can also occur in patients infected with HIV. Most significant is that most patients with advanced HIV disease are often treated with one or more medications that can affect RBC production and survival.

Before the HAART era, treatment of HIV disease with high doses of zidovudine was a major cause of myelosuppression and anemia in patients with AIDS. More recent studies, even in the era of HAART, continue to report a high prevalence of anemia among HIV-infected patients.[9] Acute and chronic inflammation is the most frequent cause of anemia in HIV infection. This is characterized by the classic findings of decreased serum iron concentration, reduced total iron-binding capacity, a normal or high ferritin level, an inappropriately low reticulocyte count for the degree of anemia, and reduced blood levels of erythropoietin. HIV infection itself may account for anemia. Therefore initiation of HAART may result in improvement or normalization of hemoglobin levels in patients who are anemic at baseline. Frequently this occurs in parallel with improvement in $CD4^+$ lymphocyte count but can occur with only marginal increase in $CD4^+$ lymphocyte numbers. The use of HIV protease inhibitors in HAART

Table 159-4 Agents for Treatment and Prevention of Opportunistic Infections With Hematologic Toxicities

Drug Class	Drug Toxicities	Hematologic
Antifungal agents	Amphotericin B deoxycholate and lipid formulations	Anemia
	Anidulafungin	Deep venous thrombosis (rare)
	Flucytosine	Bone marrow suppression
	Micafungin	Hemolysis, leukopenia
Anti-*Pneumocystis* pneumonia (PCP) agents	Dapsone	Methemoglobinemia, hemolytic anemia (especially in patients with G6PD deficiency), neutropenia
	Primaquine	Methemoglobinemia, hemolytic anemia (especially in patients with G6PD deficiency)
	Trimethoprim-sulfamethoxazole (TMP-SMX)	Bone marrow suppression
Antitoxoplasmosis agents	Pyrimethamine	Neutropenia, thrombocytopenia, megaloblastic anemia
	Sulfadiazine	Bone marrow suppression
Antimycobacterial agents	Rifampin	Thrombocytopenia, hemolytic anemia.
	Rifabutin	Neutropenia anemia, thrombocytopenia
Antiviral agents	Ganciclovir	Neutropenia, thrombocytopenia, anemia
	Interferon-α and peginterferon-α	Neutropenia, thrombocytopenia
	Ribavirin	Hemolytic anemia
	Valacyclovir	At a high dose of 8 g/day: thrombotic thrombocytopenic purpura/hemolytic uremic syndrome reported in advanced human immunodeficiency virus patients and in transplant recipients
	Valganciclovir	Neutropenia, thrombocytopenia, anemia
Antiparasitic agents	Albendazole	Neutropenia
	Benznidazole	Bone marrow suppression
	Fumagillin (investigational)	Oral therapy: neutropenia, thrombocytopenia Ocular therapy: minimal systemic effect or local effect
	Miltefosine	Leukocytosis, thrombocytosis
Treatment for syphilis	Pentavalent antimony (sodium stibogluconate)	Leukopenia, anemia, thrombocytopenia
	Penicillin G	Bone marrow suppression (rare), drug fever

PCP, Pneumocystis carinii pneumonia.

therapy also appears to improve hematopoiesis.[10] A report by the Women's Interagency HIV Study has shown that the use of HAART is associated with decreased prevalence of anemia among women.[11] HAART may also decrease the risk for anemia developing in patients who are not anemic at the initiation of therapy. Although the use of HAART is associated with decreased prevalence among people with AIDS generally, the prevalence of anemia remains high among persons with low CD4 counts.

Parvovirus B19 is a member of the Parvoviridae family and is responsible for several diseases in humans, including erythema infectiosum (fifth disease) in children, hydrops fetalis, acute arthropathy in adults, aplastic crisis in patients with chronic hemolytic disorders, and pure red cell aplasia in immunocompromised individuals. Parvovirus-induced pure red cell aplasia in association with HIV infection was described over a decade ago.[12] Parvovirus B19 infection is generally limited to human erythroid progenitor cells and leads to erythroid cell death. In hosts with normal immune responses and normal erythrocyte production, acute infection causes a self-limited (4 to 8 days) interruption in the production of erythrocytes that does not result in significant anemia. However, if host immune responses are impaired, this can result in persistent infection of erythroid precursors, leading to a prolonged and severe anemia.

The seroprevalence of parvovirus B19 infection is similar among HIV-infected and noninfected individuals. Furthermore, HIV-infected individuals who have serologic evidence of parvovirus B19 infection usually do not have evidence of active infection (i.e., Parvovirus B19 viremia). Parvovirus B19–induced red cell aplasia seen in HIV patients often occurs in individuals with low or absent levels of B19-specific antibodies.[13]

Clinically the disease presents in patients with findings consistent with profound anemia characterized by weakness, pallor, dyspnea, and tachycardia. Hemoglobin values as low as 4 to 5 g/dL and absolute reticulocyte counts of less than 5×10^9/L (<0.1%) are commonly reported. Detection of parvovirus immunoglobulin G (IgG) and IgM is not reliable because levels of antibodies may be low or undetectable among patients and are not diagnostic of acute parvovirus B19 red cell aplasia. The most reliable diagnostic study of parvovirus B19 infection is the detection of parvovirus DNA by either PCR or dot blot hybridization. Because the high sensitivity of PCR may lead to positive test results for months after the original infection, dot blot hybridization may be a better test for making a diagnosis of acute infection resulting in red cell aplasia. Histologic examination of bone marrow aspirates reveals hypocellularity, markedly decreased maturing erythrocytes, and occasional giant pronormoblasts. The presence of giant pronormoblasts in a bone marrow aspirate or biopsy specimen as shown in Fig. 159-7 is diagnostic of parvovirus B19 infection.[6]

Initial therapy for parvovirus-induced red cell aplasia should be aimed at correcting the anemia through red blood cell transfusions. Treatment with intravenous immunoglobulin (IgG) 0.4 g/kg daily for 5 days can lead to a rapid decrease in the level of parvovirus viremia, improvement in the reticulocyte count, and resolution of the anemia. Recurrence is commonly seen if there is no improvement in the patient's immunologic function. If the anemia recurs within 6 months of the initial therapy, monthly maintenance therapy with 0.4 g/kg intravenous IgG may be required. Immune reconstitution resulting from the successful use of HAART may lead to complete remission of this condition.

Anemia Due to Ineffective Red Blood Cell Production

Ineffective production of red cells can occur with deficiencies of folate or vitamin B_{12}. Ineffective production of red blood cells is frequently characterized by concomitant decreases in platelets and neutrophils accompanied by megaloblastic red cell morphology with large oval macrocytes and hypersegmented neutrophils. In addition to a low reticulocyte count, there may be elevations in indirect bilirubin and serum lactate dehydrogenase. Because of the relatively small tissue stores of folate, patients with advanced HIV disease who have poor dietary intake, excessive alcohol ingestion, and/or jejunal disease may become deficient in folate. More commonly reported in patients with advanced HIV infection is decreased serum B_{12} levels. Low serum B_{12} level has been documented in approximately one-third of patients with AIDS. Patients with advanced HIV infection (AIDS) appear to acquire gastrointestinal defects resulting in B_{12} malabsorption. The mechanisms responsible for decreased B_{12} absorption observed in these patients include both infections of and other acquired disorders of the small intestine and ileum, food B_{12} malabsorption secondary to inadequate gastric acid production, and true pernicious anemia with antibodies to the H^+/K^+ parietal cell pump and intrinsic factor. However, not all cases of low serum levels of B_{12} are associated with true metabolic B_{12} deficiency as characterized by elevated methylmalonic acid. This may be due to the finding that some patients with neutropenia secondary to a hypocellular bone marrow may have low serum levels of transcobalamin I (TCI), the major serum B_{12} carrier protein that is found in the specific granules of neutrophils. However, transport of B_{12} into cells is mediated by transcobalamin II (TCII), which carries only 25% to 30% of serum B_{12}, and for that reason the newer assays that measure B_{12} bound to TCII (holotranscobalamin II assays) may be more reflective of serum B_{12} status in neutropenic HIV-infected patients.

A diagnosis of B_{12} deficiency should include not only a low serum B_{12} level, but normal or elevated blood levels of folic acid, and elevated blood homocysteine and methylmalonic acid levels in a patient with normal renal function. With a diagnosis of B_{12} deficiency an effort should be made to determine the causes of B_{12} malabsorption and treatment begun with monthly administration of parenteral B_{12} to correct the deficiency. If anemia and cytopenias are due to the B_{12} deficiency alone, treatment should result in correction within 4 to 6 weeks. Because B_{12} deficiency is also associated with a variety of neurologic defects, including motor and sensory neuropathy; cognitive defects, including dementia; and the most severe neurologic manifestation of subacute combined degeneration of the spinal cord, the possibility of B_{12} deficiency should be considered in any HIV-infected patient with neurologic symptoms.

Anemia Due to Increased Red Blood Cell Destruction

Anemia resulting from hemolysis of RBCs can result from processes either intrinsic or extrinsic to the RBC. Examples of intrinsic defects include hemoglobinopathies, RBC membrane defects, or RBC enzyme functional deficiencies such as glucose-6-phosphate dehydrogenase (G6PD) deficiency. Exclusive of G6PD deficiency, the majority of patients with these RBC defects have a lifelong history of anemia. Diagnosis in most circumstances can be made by careful

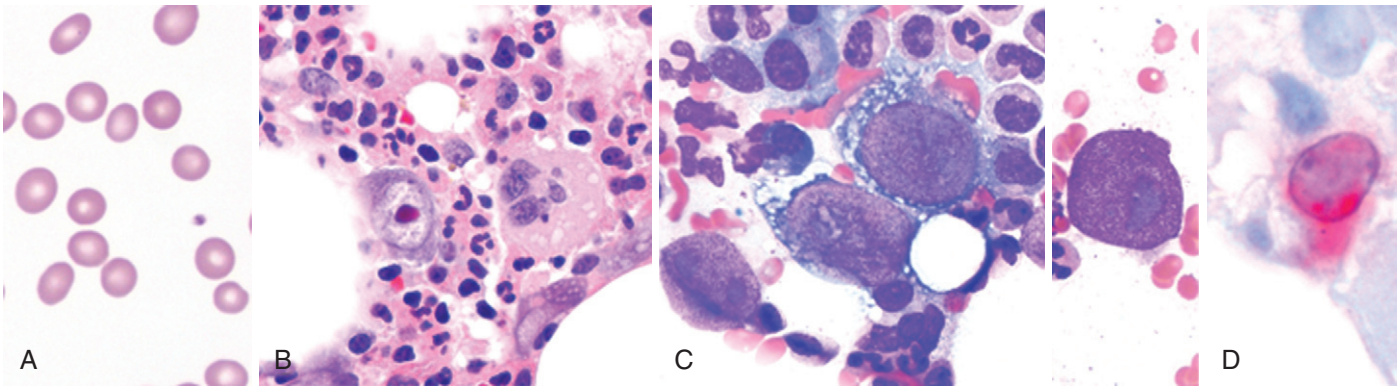

Figure 159-7 HUMAN PARVOVIRUS INFECTION IN HIV. The peripheral blood smear shows anemia with no polychromasia **(A)**. The marrow biopsy shows mostly granulocytic and megakaryocytic elements with a lack of erythroid forms **(B)**, except for rare large pronormoblasts with nuclear inclusions (**B,** *center*). On the aspirate, the large degenerating pronormoblasts have nuclear inclusions that resemble large nucleoli **(C)**. These are viral inclusions. Sometimes the pronormoblasts are totally degenerated and present as only bare nuclei with the viral inclusion still obvious (**C,** *right*). An immunostain for parvovirus in a degenerated pronormoblast is illustrated **(D)**.

review of the peripheral blood smear. G6PD deficiency is an X-linked disorder and found predominately in men. Hemolysis occurs when erythrocytes are exposed to oxidative stress. Depending upon the degree of enzyme deficiency, patients may not have had a previous documented episode of hemolysis. G6PD deficiency–associated hemolysis can occur in HIV-infected patients who are taking dapsone or trimethoprim and sulfamethoxazole combinations for pneumocystis prophylaxis or treatment. In some patients the degree of hemolysis does not result in significant anemia because RBC destruction is well compensated by effective RBC production, and patients can continue on treatment. However, patients with the Mediterranean form of G6PD may develop severe hemolysis, and treatment with such medications is contraindicated.

Extrinsic causes of RBC hemolysis observed in patients with HIV infection include microangiopathic hemolytic disorders such as thrombotic thrombocytopenic purpura (TTP; see Thrombocytopenia in HIV Infection), vasculitis, or disseminated intravascular coagulation. Patients will have associated thrombocytopenia and demonstrate RBC fragmentation on the peripheral blood smear. Autoimmune hemolytic anemia rarely occurs in HIV-infected individuals, although a positive antiglobulin (Coombs) test result is not uncommon. Patients with documented autoimmune hemolysis may respond to treatment with corticosteroids, rituximab, or splenectomy. The risk for HIV progression with the use of corticosteroids and rituximab does not appear to be an issue in patients receiving HAART.

Impact of Anemia on HIV Disease Progression and Survival

Anemia has been shown to be an independent risk factor for clinical progression of HIV disease. In patients in whom antiretroviral therapy (HAART) is to be initiated, anemia, a CD4 cell count that is less than 0.2×10^9/L, HIV viral load, and a pretreatment diagnosis of clinical AIDS are well-established risk factors for rapid disease progression. A moderate anemia with a hemoglobin level of 8 to 14 g/dL in men or 8 to 12 g/dL in women is associated with a relative hazard of disease progression or death of 2.2 (95% CI, 1.6 to 2.9; $P < 0.0001$), whereas a more severe anemia with a hemoglobin level of less than 8 g/dL has a relative hazard of 7.1 (95% CI, 2.5 to 20.1; $P < 0.0002$).

Anemia has a significant impact on overall survival in HIV-infected patients. A Baltimore study of 2348 HIV-infected patients found that a hemoglobin level of 6.5 to 8 g/dL was predictive of a threefold increased risk for death, and a hemoglobin of less than 6.5 g/dL was predictive of a fourfold increased risk for death. A European study of 6725 HIV-infected patients found the hemoglobin level at baseline was an independent prognostic factor for survival along with the $CD4^+$ lymphocyte count and HIV plasma viral load. For each 1 g/dL decrease in hemoglobin level, the relative hazard of death was 1.39 (95% CI, 1.34 to 1.43; $P < 0.0001$). Additional cohort studies from the United States, including the Multistate Adult and Adolescent Spectrum of HIV Disease Surveillance Project and the Women's Interagency HIV Study, have also confirmed that anemia is an independent risk factor for mortality in HIV-infected individuals.

Management of Anemia and the Use of Erythropoietin in HIV-Infected Patients

Treatment of anemia should be directed toward correcting the underlying cause whenever possible. The use of blood transfusion should be minimized and reserved for patients who have rapid decreases in hemoglobin levels, extremely low hemoglobin levels, or pronounced anemia-related symptoms. A number of clinical trials of antiretroviral medication combinations (HAART) have shown that suppression of HIV replication is associated with improvement in anemia. In addition, improvement of anemia on HAART has been found to occur independent of the patients' sex, race, mode of HIV infection, change in $CD4^+$ lymphocyte count, and additional therapies for anemia. Improvement in anemia, with an increase in the reticulocyte count, can be seen as early as 8 to 12 weeks, with maximum improvement usually obtained by 12 months.

Erythropoietin supplementation has been shown to be beneficial in HIV-infected patients with well-established anemia and when the hemoglobin level is decreasing or has decreased slowly. A blunted response to erythropoietin, as observed in anemia of acute and chronic inflammation, is common in HIV-infected patients with anemia. However, erythropoietin (Epogen, Procrit) therapy should be considered for refractory anemia in symptomatic patients with a hemoglobin level of less than 11 g/dL in men and less than 10 g/dL in women. The primary goal should be to maintain quality of life and functional status. Many patients may be asymptomatic with lower hemoglobin levels (9 to 10 g/dL), and physicians should use erythropoietic agents only for symptomatic patients with these lower hemoglobin levels. The initial adult dose is 40,000 units subcutaneously per week which has been shown to be equivalent to treatment three times a week at 100 to 200 units/kg.[14] Also, darbepoietin alfa given at a dose of 3.0 mcg/kg every 2 weeks has been shown to be equally effective. Onset of action as characterized by an increase in the reticulocyte count is within 1 to 2 weeks, with increased hemoglobin noted in 2 to 6 weeks. The baseline level of endogenous serum erythropoietin has been shown to be predictive of response to the therapeutic use of erythropoietin. A baseline erythropoietin level of greater than 500 International Units/L is associated with a significantly lower response to treatment. Response to erythropoietin therapy also depends on the severity of anemia, presence of active infection, and available iron stores. If the hemoglobin level fails to increase more than 1 g/dL after 4 weeks of therapy, the dose may be increased to 60,000 units weekly. After an additional 4 weeks, if the hemoglobin level does not increase by at least 1 g/dL from baseline, therapy should be discontinued. When combined with the use of HAART, erythropoietin treatment may result in a more rapid improvement in hemoglobin level but has not been shown to improve survival or statistically reduce the total number of transfusions. This may be due to the marginal contribution that erythropoietin supplementation may have in the background of the significant improvement in immune status and bone marrow function provided by effective antiretroviral therapy.[10]

LEUKOPENIA AND NEUTROPENIA: INCIDENCE AND PATHOGENESIS

Leukopenia is common in patients with advanced HIV infection, occurring in up to 85% of patients with clinical AIDS. In such patients low white blood cell counts are frequently a result of both decreased lymphocytes and neutrophils. Neutropenia ($<1.5 \times 10^9$/L) is reported in 5% to 10% of HIV-infected patients with the highest prevalence in patients with advanced HIV infection (AIDS) (see box on Neutropenia in HIV/AIDS). In a 7.5-year longitudinal study of 1729 women with HIV infection an absolute neutrophil count (ANC) of less than 1×10^9/L was documented in 31%. HIV-related risk factors for the development of neutropenia include a high level of plasma HIV viral RNA and a low $CD4^+$ lymphocyte count. In turn, the use of HAART is associated with a lower risk for developing neutropenia. Decreases in the neutrophil count are often transient, self-limiting, and rarely of clinical significance, but a neutrophil count of less than 0.5×10^9/L of prolonged duration does pose a significant risk for infection. In a study of 87 consecutive HIV-infected patients who developed neutrophil counts of less than 1×10^9/L, the median duration of neutropenia was 13 days and the nadir neutrophil count was 0.66×10^9/L. Infection occurred in only 6 (8%) of 71 evaluable patients, of which 4 patients had neutrophil counts less than 0.5×10^9/L. Ten (14%) patients had neutrophil counts less than 0.5×10^9/L and received granulocyte colony-stimulating factor (G-CSF) treatment, which artificially altered the natural history of neutropenia in this patient population.

Decrease in vitro colony growth of the colony-forming unit—granulocyte-macrophage progenitor cell has been reported, which

Neutropenia in HIV/AIDS

Leukopenia is common in patients with advanced HIV infection. Low white blood cell counts are frequently a result of both decreased lymphocytes and neutrophils. HIV-related risk factors for the development of neutropenia include a high level of plasma HIV viral RNA and a low $CD4^+$ lymphocyte count. The use of highly active antiretroviral therapy (HAART) is associated with a lower risk for developing neutropenia. Decreases in the neutrophil count are often transient, self-limiting, and rarely of clinical significance, but a neutrophil count of less than 0.5×10^9/L of prolonged duration does pose a significant risk for infection. The most common cause of neutropenia in HIV-infected patients is medication-related myelosuppression. Neutropenia is a common complication reported with many of the drugs used to treat opportunistic infections such as *Pneumocystis carinii,* toxoplasmosis, or cytomegalovirus (CMV) infection. Although neutropenia resulting from HIV-related myelosuppression often improves with HAART, antiretroviral-associated neutropenia can be observed with higher doses of zidovudine. Rare cases of agranulocytosis have been reported with the use of the antiretroviral drugs abacavir and indinavir. Other causes of neutropenia include bone marrow involvement by opportunistic infections such as *Mycobacterium avium* or CMV or bone marrow involvement with HIV-associated malignancies and their subsequent treatment. A number of acquired functional defects have been described in both neutrophils and monocytes from patients with HIV infection. Many of these defects are observed in patients with advanced disease with high levels of plasma viral RNA and $CD4^+$ lymphopenia.

Treatment of neutropenia should be guided by the underlying cause. This may require treatment of active infection or removal of medications associated with the development of neutropenia. The use of HAART has clearly been shown to reduce the risk for developing leukopenia and neutropenia and to significantly increase the neutrophil counts in treated patients. Sargramostim, or granulocyte-macrophage colony-stimulating factor (GM-CSF; Leukine), and filgrastim, or granulocyte colony-stimulating factor (G-CSF; Neupogen), are the primary pharmacologic agents used in the treatment of severe neutropenia in HIV-infected patients and have been shown in clinical studies to be safe and effective. G-CSF is indicated for drug-induced, cancer-related, and HIV-related neutropenia with an absolute neutrophil count (ANC) of less than 0.5×10^9/L. Common side effects of treatment with GM-CSF include fever, fatigue, myalgias, bone pain, and headache.

AIDS, Acquired immunodeficiency syndrome; *HIV,* human immunodeficiency virus.

may explain the neutropenia observed with HIV infection alone. Inhibitory substances produced by HIV-infected cells have been reported to suppress neutrophil growth and differentiation in vitro. A number of inflammatory cytokines, including TGF-β and TNF-α, may directly suppress myelopoiesis or inhibit the production of important myeloid growth factors, G-CSF and granulocyte-macrophage colony-stimulating factor (GM-CSF). Decreased serum levels of G-CSF have been observed in afebrile neutropenic HIV-infected patients. The HIV proteins tat and p24 have also been reported capable of suppressing myelopoiesis.

The most common causes of neutropenia in HIV-infected patients are medication-related myelosuppression. In a study of 87 consecutive HIV-infected patients with neutrophil counts of less than 2×10^9/L, only 3 patients were not receiving medications associated with a risk for neutropenia and 66% were receiving three or more myelosuppressive medications. Neutropenia is a common complication reported with many of the drugs used to treat opportunistic infections such as *Pneumocystis carinii,* toxoplasmosis, or CMV infection. These medications are listed in Table 159-4. Although neutropenia resulting from HIV-related myelosuppression often improves with HAART, antiretroviral-associated neutropenia can be observed with higher doses of zidovudine. Zidovudine-associated neutropenia resolves with dose reduction or discontinuation of the medication. In a study of 62 HIV-infected patients with neutrophil counts of 1×10^9/L or less, cancer chemotherapy, zidovudine, trimethoprim-sulfamethoxazole, and ganciclovir were the medications most commonly responsible for neutropenia. In the same report, medication-related neutropenia associated with infection was most often seen in the patients receiving cancer chemotherapy. Rare cases of agranulocytosis have been reported with the use of the antiretroviral drugs abacavir and indinavir.

Neutropenia is often observed in patients with bone marrow involvement by opportunistic infections such as *Mycobacterium avium* or CMV. Bone marrow involvement with HIV-associated malignancies and their subsequent treatment can also result in significant and prolonged neutropenia. However, malignancy treatment–related neutropenia in clinical trials appears to be less severe in patients receiving simultaneous HAART.

Abnormalities of Neutrophil and Monocyte Function

A number of acquired functional defects have been described in both neutrophils and monocytes from patients with HIV infection. Many of these defects are observed in patients with advanced disease with high levels of plasma viral RNA and $CD4^+$ lymphopenia. Impaired chemotaxis and reduced expression of leukocyte adhesion molecules necessary for migration of neutrophils to sites of infection have been reported. Decreased opsonization of antibody-coated bacteria due to Fc-receptor dysfunction and decreased superoxide production necessary for optimal intracellular killing of bacterial and fungal organisms have been observed in both neutrophils and macrophages from HIV-infected patients. Defective intracellular killing of mycobacterial and fungal organisms may also be due in part to defective production of interferon-γ.

Management of Neutropenia in HIV-Infected Patients

Impact of HAART and Use of GM-CSF and G-CSF

Treatment of neutropenia should be guided by the underlying cause. This may require treatment of active infection or removal of medications associated with the development of neutropenia. The use of HAART has clearly been shown to reduce the risk for developing leukopenia and neutropenia and significantly increasing the neutrophil counts in treated patients. The Women's Interagency HIV Study of 1729 HIV-infected women found that the use of HAART, without zidovudine, was associated with protection against developing neutropenia. In addition, HAART therapy, even incorporating zidovudine, was associated with resolution of neutropenia in women with advanced HIV disease. Another study of 66 HIV-infected patients treated with HAART reported statistically significant increases in total leukocyte and neutrophil counts after 6 months of treatment. These studies support the use of effective HAART therapy as the initial approach to the management of mild to moderate leukopenia and neutropenia in HIV-infected patients.

Sargramostim, or GM-CSF (Leukine), and filgrastim, or G-CSF (Neupogen), are the primary pharmacologic agents used in the treatment of severe neutropenia in HIV-infected patients and have been shown in clinical studies to be safe and effective. A long-term study of 105 HIV-infected patients randomized to receive weekly injections of GM-CSF (125 mcg/m^2) or placebo while receiving zidovudine antiretroviral therapy reported after 6 months of treatment that GM-CSF–treated patients were more likely to have an HIV plasma RNA level below level of detection and less zidovudine resistance mutations. A study that compared 123 HIV-infected leukopenic patients treated for 12 weeks with GM-CSF to 121 untreated leukopenic

patients showed that the total leukocyte count, including neutrophils and monocytes, increased by 65% at week 12 when compared to baseline values (P <0.001). In the untreated leukopenic HIV-infected patients, the total leukocyte count decreased by 24% below baseline values at week 12 (P <0.001). Common side effects of treatment with GM-CSF include fever, fatigue, myalgias, bone pain, and headache.

A randomized study of 258 HIV-infected patients with $CD4^+$ lymphocyte counts below 0.2×10^9/L and neutrophil counts of less than 1×10^9/L were randomized to one of two dose regimens of G-CSF (1 mcg/kg/day or 300 mcg three times a week) versus no treatment. Patients in the control group who developed severe neutropenia (<0.5×10^9/L) were then randomized to one of the treatment regimens. The intention-to-treat analysis found the incidence of severe neutropenia (<0.5×10^9/L) was 1.7% in the treated group versus 22% in the untreated controls. The incidence of bacterial infections was 31% lower in the treated group, with fewer severe bacterial infections and significantly fewer hospital days (45% reduction) for bacterial infections.

The use of G-CSF has been associated with a reduction in severe neutropenia in patients treated for CMV infection with ganciclovir (Cytovene), but the evidence is unclear as to whether it offers a clear clinical benefit. However, in general it has been shown to be safe and effective in raising leukocyte counts when administered to patients with HIV infection receiving antiretroviral therapy. G-CSF is indicated for drug-induced, cancer-related, and HIV-related neutropenia with an ANC of less than 0.5×10^9/L. The initial dose is 1 to 10 mcg/kg/day and should be titrated by 1 mcg/kg/day to obtain a neutrophil count of 1.0×10^9/L. Most patients will respond to a dose of 1 mcg/kg/day. G-CSF use should be carefully monitored and the dose reduced or stopped when the neutrophil count exceeds 1.0×10^9/L.

THROMBOCYTOPENIA IN HIV INFECTION

Thrombocytopenia, alone or in association with anemia and/or leukopenia, is frequently seen in approximately 40% of HIV-infected patients in the course of their disease. Thrombocytopenia has been reported to be the first sign of HIV infection in up to 10% of infected individuals. The most common cause of thrombocytopenia in HIV infection is HIV-related autoimmune thrombocytopenia, which is clinically indistinguishable from classic immune thrombocytopenia purpura (ITP) (see box on Thrombocytopenia in HIV Infection).

An association between AIDS and ITP was described before HIV had been isolated and characterized. HIV infects $CD4^+$ lymphocytes, monocytes, and macrophages, and some experimental evidence also documents infection of megakaryocytes. Although a number of different mechanisms have been reported by which HIV infection can produce thrombocytopenia, the ability of effective antiretroviral therapy to improve platelet counts demonstrates a clear relationship between viral replication, the expression of viral-related proteins, and the host response to platelets.

Thrombocytopenia in HIV Infection

The most common cause of thrombocytopenia in HIV infection is HIV-related autoimmune thrombocytopenia, which is clinically indistinguishable from classic immune thrombocytopenia purpura (ITP). HIV infects $CD4^+$ lymphocytes, monocytes, and macrophages, and some experimental evidence also documents infection of megakaryocytes. Thrombocytopenia is more prevalent in patients with advanced HIV infection and among intravenous drug abusers. The clinical picture of HIV-associated ITP (HIV-ITP) is often mild, with only a minority of patients having platelet counts of less than 50×10^9/L. Major bleeding is rare, and only a few cases of fatal hemorrhage have been reported. HIV-ITP is generally responsive to therapeutic interventions used in classic ITP. Despite the initial anxiety regarding the use of corticosteroids in HIV-infected, immune-suppressed patients, no deleterious effects of short-term treatment with prednisone have become evident. However, long-term treatment with corticosteroids should still be avoided, and other coinfections such as tuberculosis, cytomegalovirus, or hepatitis C should be excluded before initiating treatment with corticosteroids. Intravenous immunoglobulin (IVIg) and anti-Rh(D) are equally effective in increasing platelet counts acutely in severely affected patients. Splenectomy has proven to be safe and effective in refractory patients. Highly active antiretroviral therapy (HAART) induces sustained platelet responses in association with effective viral suppression and is the front line of treatment for HIV-associated thrombocytopenia. At present there are no data evaluating the efficacy of the newly approved thrombopoietin receptor agonists, romiplostim and eltrombopag, in the management of HIV-related thrombocytopenia, but long-term efficacy and safety data regarding the use of these agents in primary ITP would suggest that they would be effective in the management of HIV-ITP.

AIDS, Acquired immunodeficiency syndrome; *HIV,* human immunodeficiency virus.

Epidemiology

Thrombocytopenia was first associated with AIDS before the discovery of HIV. Before the use of HAART, HIV-associated thrombocytopenia (HIV-ITP; platelet count <150×10^9/L) was identified in approximately 5% to 30% of HIV-1 infected patients. Thrombocytopenia is more prevalent in patients with advanced HIV infection defined as a CD4 lymphocyte count of less than 0.2×10^9/L, clinical AIDS, and among intravenous drug abusers. The Multicenter AIDS Cohort Study of 1611 HIV-positive homosexual and bisexual men reported a platelet count of less than 150×10^9/L in 6.7%. The incidence of thrombocytopenia was only 2.8% in men with CD4 lymphocyte counts greater than 0.7×10^9/L, but rose to 10.8% in those with $CD4^+$ lymphocyte counts of less than 0.2×10^9/L. A review of 1004 HIV-infected patients seen in two HIV/AIDS clinics identified platelet counts of less than 150×10^9/L on at least one determination in 110 (11%) patients; 42 (4.2%) patients had platelet counts of less than 100×10^9/L, and 15 (1.5%) had a platelet count of less than 50×10^9/L. Thrombocytopenia was more prevalent in patients with clinical AIDS (21.2%) and a $CD4^+$ lymphocyte count of less than 0.2×10^9/L (20%).

A review of the medical records of 36,515 HIV-infected participants in the Multistate Adult and Adolescent Spectrum of HIV Disease Surveillance Project reported a 1-year incidence of thrombocytopenia of 3.7%, defined as a platelet count of less than 50×10^9/L. The incidence and severity of thrombocytopenia was associated with the stage of disease with an incidence of 1.7% among patients with HIV infection, but not clinical or immunologic AIDS, 3.1% among persons with immunologic AIDS ($CD4^+$ lymphocytes less than 0.2×10^9/L), and 8.7% in patients with clinical AIDS. By logistic regression analysis, clinical AIDS, CD4 lymphocyte count of less than 0.2×10^9/L, age above 45 years, intravenous drug use, lymphoma, and/or anemia, were associated with a platelet count of less than 50×10^9/L.

An increased incidence and severity of thrombocytopenia in HIV-infected intravenous drug users compared to HIV-infected homosexuals has been reported. Mientjes et al[14] reported a platelet count of less than 150×10^9/L in 29/182 (16.4%) homosexual HIV-infected men compared with 38/103 (36.9%) HIV-infected intravenous drug users. None of the homosexual men had a platelet count of less than 50×10^9/L, whereas 6 (5.8%) intravenous drug users had a count of less than 50×10^9/L. These differences may be explained in part by the higher incidence of coinfection with hepatitis C and underlying liver disease in HIV-infected intravenous drug users.

In a prospective multicenter cohort study of 738 HIV-infected hemophilia patients, the incidence over time of HIV-related conditions was determined in 130 children and 193 adults. The 10-year

cumulative incidence of thrombocytopenia (platelets $<100 \times 10^9$/L) after seroconversion was 43% ± 7% in adults and 27% ± 6% in children. The mean CD4 counts were significantly higher in children (514 ± 61 cells/μL) than adults (260 ± 24 cells/μL) with thrombocytopenia ($P = .0004$).

Most clinical data were obtained before the widespread use of HAART therapy in patients with early HIV infection. There is little data on the current prevalence of thrombocytopenia in patients under active antiviral treatment. However, recent prospective data from the Women's Interagency HIV Study have documented a reduction in the incidence of anemia and neutropenia in HIV-infected women on HAART therapy. These findings are in accord with the impression that there has been a similar reduction in the incidence of thrombocytopenia, especially platelet counts of less than 50×10^9/L in compliant patients.

Pathophysiology

Multiple mechanisms may contribute to the development of chronic ITP (CITP) in the HIV-infected patient, and these have recently been reviewed. Proposed mechanisms include accelerated platelet clearance due to immune complex disease, and antiplatelet glycoprotein antibodies and/or anti-HIV antibodies that cross-react with platelet membrane glycoproteins (antigenic mimicry). The ability of HIV-1 to rapidly mutate may facilitate both its ability to escape immune surveillance and to mimic host antigens. Direct infection of megakaryocytes results in defective platelet production and megakaryocytic apoptosis.

Epidemiologic studies suggest that the pathogenesis of thrombocytopenia is partially dependent on disease burden. HIV-ITP developing early after infection more often resembles classic ITP in which thrombocytopenia is mediated primarily by peripheral destruction, whereas thrombocytopenia in patients with immunologic AIDS (CD4 lymphocytes $<2 \times 10^9$/L) is attributable predominately to decreased platelet production and ineffective hematopoiesis. Although platelet counts may improve with antiretroviral therapy in both patient populations, patients with advanced disease are less likely to respond to classic primary ITP therapy such as splenectomy, corticosteroids, intravenous immunoglobulin, or anti-Rh(D). Initial studies of HIV-associated ITP suggested that an immune complex mechanism was responsible for the thrombocytopenia, wherein platelets were cleared from the circulation as "innocent bystanders." More recent studies have shown that these immune complexes contain antibodies that cross-react with both HIV and platelet glycoproteins. These antibodies also cross-reacted with sequences on HIV nef, gag, env, and pol proteins. Similar cross-reactivity between HIV viral proteins and platelet glycoproteins has been reported in the studies of Bettlaieb et al,[15] who eluted immunoglobulin from platelets from patients with HIV-ITP and found these antibodies bound to antigenic epitopes common to both platelet GPIIIa and HIV GP160.

Studies of platelet kinetics have demonstrated that HIV-ITP is frequently associated with decreased platelet production. Megakaryocytes express the CD4 receptor and coreceptors necessary for HIV infection. Cytopathic infection of HIV of the megakaryocyte has been demonstrated and is the postulated primary mechanism for impaired megakaryopoiesis. However, the potential of cross-reactive antibodies between HIV-related proteins and platelet glycoproteins capable of inducing apoptosis of megakaryocytes as has been described with primary ITP has not been studied.

Clinical Manifestations

HIV-seropositive patients can develop thrombocytopenia several years before the development of overt AIDS, and the early disease is clinically indistinguishable from classic ITP. However, the clinical picture of HIV-ITP is often mild, with only a minority of patients having platelet counts of less than 50×10^9/L. Major bleeding is rare, and only a few cases of fatal hemorrhage have been reported. There has been greater variability in patients with hemophilia A. For example, in one report of thrombocytopenia (platelets $<100 \times 10^9$/L) in 14 of 124 (11%) hemophiliacs, only 1 patient had a major hemorrhage. In contrast, in another report of patients with a platelet count of less than 100×10^9/L in 30 of 87 (34%) hemophiliac patients, with 11 (13%) having a platelet count of less than 50×10^9/L, 9 of the 11 patients (82%) had major bleeding complications and 3 suffered fatal hemorrhage.

Severe thrombocytopenia in patients with advanced HIV infection is frequently associated with additional cytopenias. In a study of 52 HIV-infected intravenous drug users with thrombocytopenia, 4 patients (8%) with advanced HIV infection had a hypocellular bone marrow examination and pancytopenia. HIV-infected drug users were also more likely to have antibodies to both hepatitis B and C and to have abnormal liver function studies. The role of immune-mediated platelet destruction versus bone marrow failure in patients with advanced HIV disease is still uncertain.

Treatment of HIV-ITP

HIV-ITP is generally responsive to therapeutic interventions used in classic ITP. Therapy with prednisone produces a major hematologic response (platelet count $>100 \times 10^9$/L) in over half of all patients, although only a minority will maintain a platelet count of greater than 50×10^9/L after cessation of steroids. Despite the initial anxiety regarding the use of corticosteroids in HIV-infected, immune-suppressed patients, no deleterious effect of short-term treatment with prednisone has become evident. However, long-term treatment with corticosteroids should still be avoided, and other coinfections such as tuberculosis, CMV, or hepatitis C should be excluded before initiating treatment with corticosteroids. Intravenous immunoglobulin (IVIg) and anti-Rh(D) are equally effective in increasing platelet counts acutely in severely affected patients, but a crossover study clearly demonstrated a longer duration of response with the latter agent.

Splenectomy has proven to be safe and effective in refractory patients with HIV-TP. After splenectomy, there is a transient increase in the peripheral blood CD4 lymphocyte count, which reflects redistribution from the splenic pool into the circulation rather than an improvement in the patient's immunologic status.

HIV-related hematologic cytopenias have been shown to correlate with plasma viral load. Effective antiretroviral therapies have resulted in improvement in several HIV-related cytopenias, including HIV-CITP. Zidovudine monotherapy increased platelet counts in 60% to 70% of HIV-CITP patients. Although other antiretroviral drugs have been shown to improve hematologic parameters in patients with advanced HIV infection, their efficacy as monotherapy for the management of HIV-CITP is less well documented. Use of HAART in both de novo and zidovudine-refractory HIV-CITP has induced sustained platelet responses in association with effective viral suppression.

Responses to zidovudine and HAART may be more limited in HIV-infected intravenous drug users, possibly reflecting the impact of associated liver disease and infection with hepatitis C virus. In a prospective placebo-controlled, double-blind, randomized trial, 12 of 14 (86%) zidovudine-refractory HIV-infected intravenous drug users with elevated serum alanine aminotransferase levels suggestive of underlying liver disease who were treated with interferon-α had a statistically significant increase in their platelet counts by week 4 of therapy. Similar responses to interferon-α therapy alone have been reported in HIV-seronegative, hepatitis C virus–infected patients. An open label trial of interferon-α in a cohort of predominately homosexual men documented responses in 9 of 16 (56%) patients, with responses occurring as early as 2 weeks after the initiation of treatment. Such rapid responses preclude the possibility that improvement in the platelet count is due solely to suppression of concomitant hepatitis C virus infection. At present there are no data evaluating the efficacy of the new approved thrombopoietin receptor agonists, romiplostim and eltrombopag, in the management of HIV-related

thrombocytopenia, but long-term efficacy and safety data regarding the use of these agents in primary ITP would suggest that they would be effective in the management of HIV-ITP.

THROMBOTIC MICROANGIOPATHY AND THROMBOTIC THROMBOCYTOPENIC PURPURA

Thrombotic microangiopathy, including both TTP and the hemolytic uremic syndrome (HUS), is a well-described complication of HIV infection seen in approximately 1% of patients. The incidence of this complication appears to have decreased with the advent of HAART therapy. The incidence of TTP appears to be similar to that observed in the general population, whereas HUS appears more frequently in patients with advanced HIV infection.

TTP can occur anytime in the course of HIV infection and has been reported in some patients to be the initial manifestation of HIV infection. This life-threatening disorder is characterized by thrombocytopenia and microangiopathic (fragmentation) hemolytic anemia. The original description of this disorder emphasized a classic pentad of fever, thrombocytopenia, microangiopathic hemolytic anemia, renal failure, and neurologic abnormalities. However, most patients present with only one or two manifestations of the original pentad, and isolated thrombocytopenia may be the initial finding. Therefore it is essential that the evaluation of thrombocytopenia include a careful review of the peripheral blood smear.

TTP is the result of a failure to process endothelial-derived high-molecular-weight von Willebrand factor due to an absence of or inhibitor to the von Willebrand factor cleaving protease (a disintegrin and metalloproteinase with thrombospondin motifs [ADAMTS13]). Measurement of ADAMTS13 activity before the initiation of plasma exchange will report levels nearly always less than 10%, and additional assays will often detect an inhibitor to the protease. First-line therapy is daily plasma exchange until remission and maintenance of platelet count at 150×10^9/L, though there are a number of reported differences in how to use plasma exchange in the management of this disorder. Initial plasma exchanges should be at least a 1.5 plasma volume exchange. Corticosteroids such as prednisone (1 mg/kg/day) also can be given with the exchanges. If plasma exchange is not immediately available, infusion of fresh frozen plasma alone has been shown to be effective in patients with HIV-associated TTP. In classic TTP, relapses can occur in up to 30% of patients; however, relapse in HIV-associated TTP appears to be less frequent. Patients who relapse can be treated with repeat exchange combined with immunosuppressive therapy including agents such as vincristine or rituximab.

HUS most likely results from endothelial perturbation secondary to either HIV or other viral infections such as CMV or is drug or toxin induced, such as observed with *Escherichia coli* 0157:H7 infection. Recent data suggest that the primary event leads to unregulated complement activation due to either inhibitors of complement regulatory protein such as complement H or congenital abnormalities in complement regulation. In these patients measurement of ADAMTS13 activity will uniformly report levels near normal and above 30%. Many patients will respond to aggressive plasma exchange, but complete remissions are rare. Recently the inhibitor of complement C5a, eculizumab, has been approved for the treatment of atypical HUS, but there are no reports of its use in HIV-associated HUS.

THROMBOEMBOLIC DISEASE

Since the beginning of the AIDS epidemic, an unexpectedly high incidence of venous thromboembolism (VTE) has been observed among people with HIV disease (see box on Thromboembolic Disease in HIV/AIDS). The most compelling data in support of an increased risk for VTE in HIV disease estimated the incidence of thrombosis in their HIV-infected population to be about 2.6 per 1000 person-years. Given the fact that cohorts of patients with HIV infection tend to include a disproportionate number of younger individuals compared with the general population, this figure represents an increased incidence of VTE. The increased incidence in venous thrombosis was disproportionately greater among patients with clinical AIDS, those older than 45 years, those with AIDS-defining illnesses (particularly CMV infection), and those taking indinavir (Crixivan) or megestrol acetate (Megace). However, 53% of the thrombotic events occurred in individuals without history of recent hospitalization.

In a study comparing the risk for VTE in HIV-infected patients to an age-matched uninfected control population, there was no statistical difference in the overall risk for VTE (2.8% HIV-infected patients versus 1.8% controls) except in the HIV-infected patients less than 50 years of age (3.31% HIV-infected patients versus 0.53% controls; $P < 0.0001$). A study of 37,535 HIV-infected veterans compared to 37,535 age-, race-, and site-matched uninfected controls found a 39% increased incidence in VTE in the pre-HAART era (before 1996) and a 33% increased incidence in the era of HAART therapy. The increased risk for thrombosis was independent of a diagnosis of malignancy, HIV-related opportunistic infections, or the use of central catheters. The development of a thromboembolic event was associated with statistically increased mortality in all groups.

Thromboembolic Disease in HIV/AIDS

The estimated incidence of thrombosis in the HIV-infected population is about 2.6 per 1000 person-years. Given the fact that cohorts of patients with HIV infection tend to include a disproportionate number of younger individuals compared with the general population, this figure represents an increased incidence of venous thromboembolism (VTE). The increased incidence in venous thrombosis is disproportionately greater among patients with clinical AIDS, those older than 45 years, those with AIDS-defining illnesses, and those taking indinavir (Crixivan) or megestrol acetate (Megace). With advancing HIV disease, there are progressive prothrombotic hemostatic changes, specifically a decrease in protein S and an increase in factor VIII. It is well established that antiphospholipid antibodies (anticardiolipin antibodies [ACA] and lupus anticoagulant) are associated with a hypercoagulable state. The incidence of elevated ACA in asymptomatic HIV disease is reported to be as high as 50% and even higher in patients with clinical AIDS. Certain protease inhibitors (indinavir) have been found to be associated with VTE. The overall management principles and goals of therapy for VTE are the same for people with and without HIV infection, although extra caution is needed to anticipate possible drug interactions with highly active antiretroviral therapy (HAART), particularly with the use of warfarin.

AIDS, Acquired immunodeficiency syndrome; *HIV,* human immunodeficiency virus.

Role of Inflammation and Its Effect on the Protein C and S Anticoagulant System

With advancing HIV disease, there are progressive prothrombotic hemostatic changes, specifically a decrease in protein S and an increase in factor VIII. There is a well-documented association between acute and chronic inflammation and activation of the hemostatic system. Inflammatory cytokines such as TNF-α, IL-1, and IL-6 have been shown to activate coagulation and downregulate activation of protein C. Activated protein C (APC) is a major inhibitor of coagulation, degrading activated coagulation factors VIIIa and Va. Inflammation can also result in a decrease in functional protein S, the cofactor of APC, which most likely explains the acquired protein S deficiency observed in some HIV-infected patients, without and with thrombosis.

An important additional component of the inflammatory state, which further contributes to an increased risk for thrombosis, is the inflammation-induced increase in factor VIII coagulant protein. Factor VIII levels greater than 1500 units/L (150%) are an independent risk factor for idiopathic VTE. A study of 94 HIV-infected women and 50 HIV-negative controls who were participants in the Women's Interagency HIV Study documented a progressive prothrombotic state with advancing HIV disease characterized by progressive decreases in protein S activity associated with a progressive increase in factor VIII activity. The decreases in protein S activity and reciprocal increases in factor VIII activity closely correlated with decreasing $CD4^+$ lymphocyte count and were most significant in the women with clinical AIDS. This study provides evidence for a link between advancing HIV disease characterized by decreasing $CD4^+$ lymphocyte count and the development of clinical AIDS with opportunistic infections and hemostatic changes associated with an increased risk for venous thrombosis. This acute and chronic inflammatory state is the most likely pathogenic mechanism for development of VTE in HIV-infected individuals.

Anticardiolipin Antibodies

It is well established that antiphospholipid antibodies (anticardiolipin antibodies [ACAs] and lupus anticoagulant) are associated with a hypercoagulable state. The incidence of elevated levels of ACA in asymptomatic HIV disease is reported to be as high as 50% and even higher in patients with clinical AIDS. Recent reports have documented the presence of ACAs in HIV-infected individuals with VTE. However, two small studies reported no correlation between high levels of ACA and thrombosis in HIV infection. Because the increased thrombotic risk associated with the antiphospholipid antibody syndrome is predominantly associated with the lupus anticoagulant and β_2-glycoprotein 1, it is not surprising that increased level of ACA alone was not associated with a significantly increased risk for thrombosis. Thus the contribution of antiphospholipid antibodies to the development of VTE in HIV disease remains unknown and will require larger prospective studies that include assays for the lupus anticoagulant and anti–β_2-glycoprotein antibodies.

Role of Protease Inhibitors

Several investigators have found protease inhibitors to be associated with VTE. Sullivan et al[16] reported that the use of indinavir was associated with an increased risk for VTE. In a case series, George et al[17] reported unexplained thrombosis in HIV patients receiving protease inhibitors. Abnormalities of glucose metabolism and serum lipids are commonly observed with protease inhibitor therapy. These include acquired insulin resistance, increased levels of low-density–lipoprotein cholesterol, and decreased levels of high-density–lipoprotein cholesterol. Insulin resistance is associated with acquired defects in the fibrinolytic system, including increased levels of plasminogen activator inhibitor and tissue plasminogen activator. Similar fibrinolytic abnormalities have been observed in patients with documented insulin resistance who are treated with protease inhibitors.

High-density–lipoprotein cholesterol has been shown to significantly enhance the activity of the APC complexed with protein S. This APC complex plays an essential role in downregulating thrombin generation. The lipoprotein abnormalities associated with the use of protease inhibitors, when combined with other acquired defects in the protein C anticoagulant pathway, may further depress the anticoagulant activity of the APC complex and subsequently promote increased thrombin generation. Thus there are a number of pathogenic mechanisms that could predispose HIV-infected patients to VTE. The majority of reported hemostatic abnormalities appear primarily to affect the protein C and S inhibitory mechanisms. However, the available studies reporting an increased risk for VTE in HIV disease are only suggestive at present because most supporting data come from case reports and one uncontrolled retrospective study. Larger prospective studies are needed to assess the true relative risk for VTE in HIV-infected individuals and to determine the primary pathogenic mechanisms responsible for thrombosis in this population.

Management of VTE With HIV Infection

The overall management principles and goals of therapy for VTE are the same for people with and without HIV infection, although extra caution is needed to anticipate possible drug interactions with HAART, particularly with the use of warfarin. Initial therapy for the patient presenting with deep vein thrombosis and/or pulmonary emboli involves the use of either intravenous unfractionated heparin (UFH) or preferentially subcutaneous low-molecular-weight heparin (LMWH). Oral anticoagulants can be started immediately upon achieving therapeutic heparin levels, and under optimal circumstances heparin treatment can be completed and the patient discharged from the hospital within 5 to 7 days. LMWH preparations given subcutaneously without monitoring have been shown to be safe and effective treatment for VTE and may be preferable because they also allow for safe outpatient management. In a metaanalysis of clinical trials comparing LMWH with UFH, LMWH preparations were associated with a lower risk for major bleeding compared with adjusted-dose intravenous UFH.

The greatest difficulties in the management of VTE in HIV-infected patients occur with the use of oral anticoagulants. The optimal therapeutic range for oral anticoagulation with warfarin in patients with VTE is a prothrombin time (PT) international normalized ratio (INR) of 2 to 3. No data suggest that HIV-infected patients require a different degree of anticoagulation. However, most studies have found that general medical patients managed as outpatients have a therapeutic INR in only 60% of assays. Although there are no published data regarding the use of oral anticoagulants in HIV-infected patients, individuals receiving HAART appear to have greater difficulty in maintaining therapeutic anticoagulation, most likely due to complex drug interactions. With a reported annual risk for major bleeding with oral anticoagulants of 2% to 3% and bleeding-related fatality of 20%, careful PT monitoring of HIV-infected patients is mandatory. They should be monitored at least weekly for the first 6 to 8 weeks and should then have their PT checked every 2 weeks. In patients in whom maintaining therapeutic levels is difficult, home monitoring using devices approved by the U.S. Food and Drug Administration may be indicated. Patients who have significant difficulty maintaining a therapeutic INR or have had bleeding complications because of poor control of their anticoagulation can be treated with long-term LMWH as has been recommended for the long-term management of cancer-related VTE. In both HIV-infected and HIV-negative patients with malignancies who develop VTE, long-term management with LMWH appears to be associated with a significantly lower risk for recurrent VTE.

Oral anticoagulation in the patient with VTE should be maintained for at least 6 months. Patients with unprovoked VTE who have had major pulmonary emboli, recurrent thromboemboli, or underlying inherited or acquired prothrombotic defects may benefit from longer courses of oral anticoagulation. However, the decision to extend anticoagulation to prevent recurrence of thrombosis must be weighed against the significant risk for bleeding in this population.

CHAPTER 160

HEMATOLOGIC ASPECTS OF PARASITIC DISEASES

David J. Roberts

Parasitic diseases are not common in medical, let alone hematologic, practice in North America or Europe. However, much of the world's population are infected and become symptomatic from a plethora of parasites, and many of these infections represent global public health problems.

Although some significant parasitic diseases are transmitted in temperate climates, the majority of parasites of significance to human health are endemic in the tropical world. This reflects not only socioeconomic circumstances but also the origin of our species in tropical Africa, where the human host, parasites, and also vectors have established complex relationships over evolutionary timescales.[1] Notwithstanding such geographic variation in the incidence of parasitic disease, both travelers and recent immigrants now present to hematology clinics and laboratories all over the world with increasing frequency. Even here, there are marked variations in practice in North America and Europe, where the United Kingdom reports more cases of imported malaria than the United States and indeed has a 10-fold greater incidence of malaria per capita, reflecting the increased frequency of travel to and from endemic areas compared to North American populations.

Malaria, leishmaniasis, trypanosomiasis, and babesiosis may present directly or indirectly to hematologists. This account will concentrate on the biologic, clinical, and hematologic features of these infections and the hematologic aspects or complications of their treatment. Comprehensive accounts of the general medical aspects of these diseases are provided in many recent textbooks.[2-4]

MALARIA

Malaria is a major public health problem in tropical areas, and it is estimated that it is responsible for 600,000 to 900,000 deaths annually and 150 to 300 million infections.[5] The vast majority of morbidity and mortality from malaria is caused by infection with *Plasmodium falciparum,* although *Plasmodium vivax, Plasmodium ovale,* and *Plasmodium malariae* also are responsible for human infections. Recently a fifth species, *Plasmodium knowlesi,* has been shown to cause human infection in some parts of Southeast Asia (for review see reference 5). In endemic areas, a significant proportion of the mortality and morbidity is due to anemia. In Europe and North America, malaria is not infrequently a clinical problem in travelers or recent arrivals from malaria-endemic areas, and hematologists may be involved in the diagnosis and management of the disease. Moreover, in nonendemic areas, malaria may cause a fatal transfusion-transmitted infection, and detection of blood donors who may be carrying the disease represents a major challenge for blood services.

Epidemiology

Approximately 1000 million people live in areas of endemic or epidemic malaria. The global mortality and morbidity have been revised to 350 million cases and 1 million deaths per year following an evaluation of the prevalence of infection in Southeast Asia (Fig. 160-1). There is substantial evidence that the incidence of severe disease is now falling, sometimes spectacularly, in many parts of Africa following the widespread introduction of artemisinin combination treatment, impregnated bed nets, and residual spraying because the resources available for malaria control have increased substantially through the Global Fund and the World Health Organization's "Roll Back Malaria" campaign (www.rbm.who.int/).[6]

The distribution of malaria is determined by features of host, vector, and parasite. In summary, the global distribution of autochthonous or endogenous malaria is limited by the lower temperature limits for development of the parasite in the mosquito (sporogony) of 20° C for *P. falciparum* and 15° C for other human malarias. Within these limits transmission does not occur above 1500 m in arid regions or in the Central and South Pacific (due to the absence of suitable vectors). In addition, *P. vivax* malaria is rare in Africa where the population frequency of the blood group Duffy negative ($Fya^{-}Fyb^{-}$) is high. *P. ovale* requires a lengthy period of sporogony and is confined to areas of Africa and Southeast Asia with a high density of susceptible *Anopheles* spp. *P. knowlesi* is transmitted from macaque monkeys in forest areas of Borneo, Malaysia, Thailand, and Vietnam.[5]

In some malarious areas the seasonal pattern of clinical malaria is determined by the increase in vector density after rainfall, leading to an increase in new infections as transmission increases. In naive individuals, parasites can cause chronic infection lasting many months.

The intensity of transmission determines the distribution of clinical symptoms in different age-groups.[7] In general, in areas of high transmission younger children suffer from severe disease. Where transmission is less intense, older children suffer from severe disease. Finally, if the rate of transmission is very low, few cases of malaria are seen in any age-group and such populations would have little natural immunity. In such areas, a sudden increase in vectorial capacity (through the accidental introduction of efficient vectors or higher density, biting, or survival of the resident vectors), more rapid parasite sporogony, or migration of infected or nonimmune populations can result in epidemics where large numbers fall ill in all age-groups. The transition from high to low transmission has been classified by holoendemicity, hyperendemicity, mesoendemicity, and hypoendemicity. These categories can be related epidemiologically to age-specific rates of parasite prevalence or splenomegaly and theoretically to the reproductive ratio of malarial infection.[8]

Malaria exerts a substantial selection for human traits that protect from infection. Sickle cell trait and thalassemia traits protect from infection and are truly polymorphic characteristics in many parts of the world. Understanding the genetic epidemiology has provided the foundation of population genetics and has provided classic examples of principles of genetic selection in vivo—for example, balancing selection for sickle cell trait and negative epistasis for sickle cell trait and α-thalassemia. The homozygous forms of these characteristics cause significant clinical disease, for example, sickle cell disease, β-thalassemia, and glucose-6-phosphate dehydrogenase reduced (G6PDH) deficiency. In endemic areas, these genetic diseases represent major public health problems (for review see references 9 and 10).

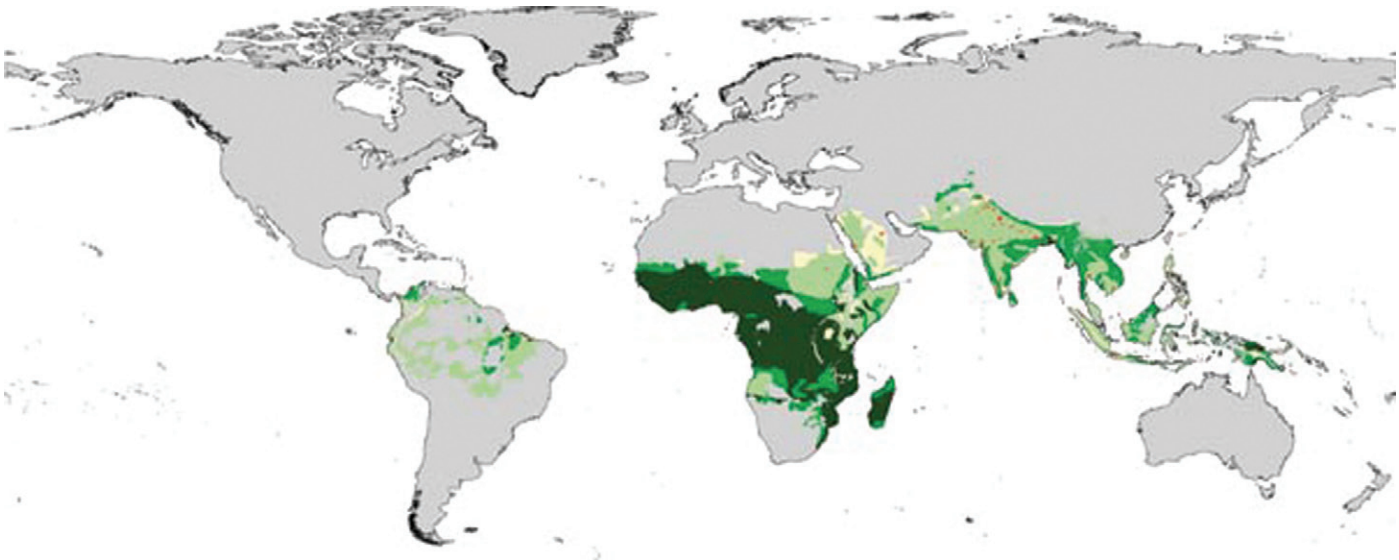

Figure 160-1 GLOBAL MALARIA ENDEMICITY. Areas are colored according to malaria endemicity (prevalence): *light green,* hypoendemic (areas in which childhood infection prevalence is less than 10%); *medium green,* mesoendemic (areas with infection prevalence between 11% and 50%); *dark green,* hyperendemic and holoendemic (areas with an infection prevalence of 50% or more); unclassified areas *(yellow)* represent only 6% of the global population at risk and are due to discrepancies in recent data. Grey areas are a combined mask of areas outside of the transmission limits and areas of population density less than 1 person/km^2. *(Data from Snow RW, Guerra CA, Noor AM, et al: The global distribution of clinical episodes of* Plasmodium falciparum *malaria,* Nature *434:214, 2005.)*

Parasitology

In *P. falciparum* (see later for a discussion of the other human parasites) the infective sporozoite forms are inoculated into the bloodstream from the salivary glands of a female *Anopheles* mosquito (Fig. 160-2). These thin, needle-shaped cells, 10 to 12 μm in length, circulate briefly with a half-life of approximately 30 minutes, before traversing macrophages and several hepatocytes before residing in a single hepatocyte.[11,12] Here rapid multiplication takes place over 5 to 8 days to produce a liver schizont, 80 μm in diameter and containing 30,000 ± 10,000 merozoites that are released into the bloodstream, where they infect erythrocytes.[13] When ready to leave hepatocytes, the parasite induces cell death in the hepatocytes and causes the release of merozoites in membrane-enclosed structures or merosomes that are extruded from the infected cell, so avoiding host cell defense mechanisms.[14]

The merozoites bind and then invade red blood cells (for review of red cell and merozoite interactions see reference 15). The host plasma membrane is invaginated to form the parasitophorous vacuole. For the first 10 hours, the developing parasites appear as fine "ring forms." Between 10 and 15 hours, the cytoplasm thickens, and 16 hours after invasion granules of the black pigment hematin, the end product of hemoglobin digestion, begin to appear. Ligands are expressed at the surface of the infected red blood cell that mediate adhesion to host receptors on venular endothelium. These trophozoites no longer circulate throughout the body but are sequestered in the peripheral circulation. Nuclear division begins, at approximately 30 hours, to form schizonts, containing up to 32 merozoites. At 48 hours, the red blood cell is ruptured to release the merozoites into the circulation to continue further cycles of asexual multiplication.

The erythrocytic cycle of schizogony may achieve a 10-fold increase in parasitemia in vivo and a patent or microscopically detectable infection 6 days after the liver stage is completed. After two or more cycles, the infection becomes clinically apparent by the paroxysms of fever that accompany the release of merozoites. Cycles of schizogony continue until the rate of parasite multiplication is reduced by chemotherapy, specific or nonspecific defense mechanisms, or occasionally, the demise of the host.

Some merozoites do not multiply but become committed during the previous erythrocytic cycle to form male or female gametocytes.[16] Gametocytes are distinguished by dispersed pigment in a single

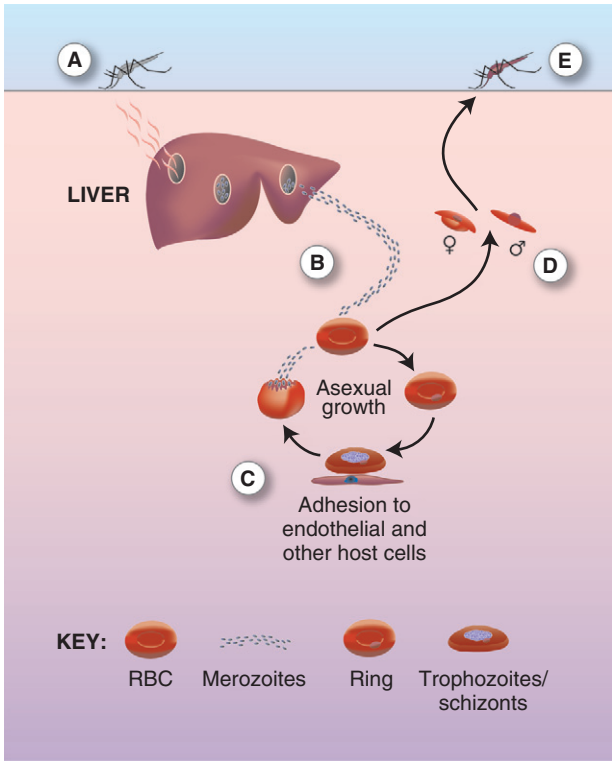

Figure 160-2 PLASMODIUM LIFE CYCLE. **A,** The asexual life cycle begins when sporozoites from a female mosquito taking a blood meal enter the circulation and invade hepatocytes. **B,** Up to 10,000 merozoites are formed. Following rupture of the hepatocyte, infective merozoites are released and invade erythrocytes (RBC). **C,** Within RBC, the parasite develops through the stages of rings, trophozoites, and schizonts. Mature schizonts burst to release erythrocytic merozoites that invade new RBC. **D,** A small proportion of merozoites in RBC transform into male and female gametocytes that are ingested by the mosquito. **E,** The male and female gametes fuse and transform into an oocyst, which divides asexually into many sporozoites that migrate to the salivary gland from where they are released during the next blood meal.

nucleus, in a fully grown parasite, and are sequestered for the first 5 days of their development in the peripheral circulation. Thus 8 to 10 days after the start of clinical infection, mature, crescent-shaped gametocytes appear in the blood.

The sexual phase (or sporogony) of the parasite life cycle begins after a male and female gametocyte are ingested by a feeding female *Anopheles* mosquito. In the midgut of the mosquito the gametocytes shed the red blood cell membrane. This change is apparently precipitated by the drop in temperature. A female gametocyte forms a single macrogamete, but male gametocytes undergo several rounds of nuclear division to produce flagellated microgametes. These microgametes are motile and migrate to fertilize a macrogamete. The resulting zygote enlarges to form a mobile ookinete and migrates through the epithelial wall of the mosquito midgut to rest finally on the external surface. The oocyst divides repeatedly to form up to 10,000 sporozoites, which travel up through the hemolymph to enter the acinar cells of the salivary glands. Once here they are infective when injected into the host.

Major differences exist in the life cycles of other human *Plasmodium* spp. First, in *P. vivax* and *P. ovale* infections, some sporozoites entering the liver form dormant hypnozoites that only begin to divide after a variable period of some months to cause further blood-stage infections or relapses. Second, the cycle of erythrocytic development in *P. malariae* takes 72 hours and thus causes quartan fever (i.e., on days 1 and 4).

The Pathophysiology of Malarial Anemia

Malaria gives ample reasons for both increased red cell destruction and reduced red cell production (see Fig. 160-3 for overview).

Loss of Infected Erythrocytes

Destruction of red blood cells is inevitable as parasites complete their 48-hour growth cycle and lyse their temporary host cell. Some parasites may be removed from erythrocytes as immature ring forms by phagocytic cells, leaving the red blood cells with residual parasite antigens to continue to circulate, albeit with reduced survival.[17] Infected erythrocytes may also be phagocytosed by macrophages following opsonization by immunoglobulins and/or complement components.[18,19] Other signals for recognition of infected erythrocytes by macrophages include abnormally rigid membranes and exposure of phosphatidylserine and other altered host antigens.[20-22]

Loss of Uninfected Erythrocytes

The activity and the number of macrophages are increased in malarial infection, and increased removal of uninfected cells may occur. Moreover, the signals for recognition of uninfected erythrocytes for removal

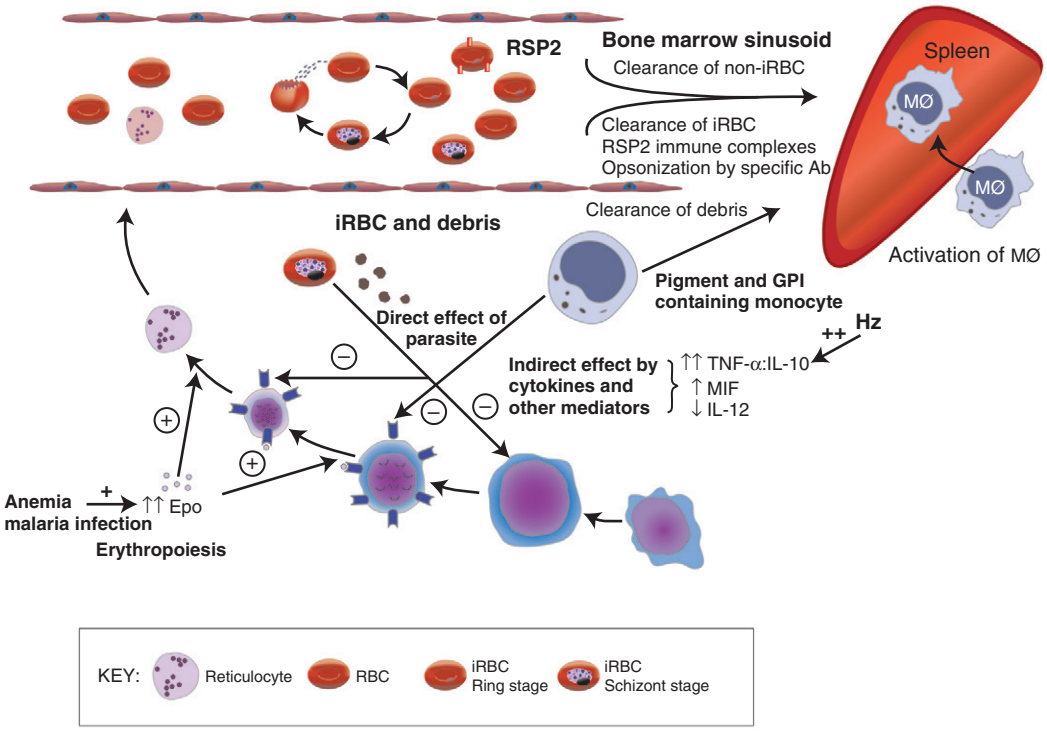

Figure 160-3 PATHOGENESIS OF MALARIAL ANEMIA. Severe malarial anemia is characterized by destruction of infected red blood cell (iRBC) following schizogony and clearance of both iRBC and uninfected RBC. During malarial infection, changes in membrane protein composition occur, and the resultant immune complexes of RBC, Ag, and immunoglobulin (Ig) (e.g., RBC-RSP2-Ig) are cleared by macrophages to the spleen, where they become activated. Pigment-containing macrophages may release inflammatory cytokines and other biologically active mediators such as 4-hydroxynonenal (HNE). Macrophage inhibitory factor (MIF) may be released by macrophages or a plasmodial homologue may suppress erythropoiesis. Malarial pigment or other parasite products may have a direct inhibitory effect on erythropoiesis. Inhibition of erythropoiesis may be at one or more sites in the growth and differentiation of hematopoietic progenitors. Both indirect and direct effects may cause suppression of the bone marrow and spleen resulting in inadequate reticulocyte counts for the degree of anemia. *Ab,* Antibody; *Ag,* antigen; *Epo,* erythropoietin; *GPI,* glycosylphosphatidylinositol anchors of merozoite proteins; *Hz,* hemozoin; *IL,* interleukin; *Mϕ,* macrophage; *RSP2,* ring surface protein-2; *TNF-α,* tumor necrosis factor-α.

by macrophages are enhanced. Uninfected erythrocytes bind increased amounts of immunoglobulin and/or complement as detected in the direct antiglobulin test (DAT or Coombs test).[23] These antibodies do not have a particular specificity but are more likely to represent immune complexes absorbed onto the surface of red blood cells.[23] Furthermore, hemozoin may activate complement directly and cause deposition of C3b on uninfected red blood cells.[24] However, an association between positive DAT results and severe anemia has not been established.[25] More recent studies have shown that red cells from malaria patients were not only more susceptible to phagocytosis but also red cells from children with acute malaria showed increased surface IgG and low levels of red cell CR1 and CD55 compared with controls.[26]

Role of the Spleen

Some degree of splenomegaly is a normal feature of malarial infection, and the prevalence of splenomegaly in regions of malarial transmission is used as a major indicator of the level of malarial endemicity. The importance of the spleen in host defense against malaria has been demonstrated in experimental systems, and individuals whose spleens have been surgically removed are thought to be more susceptible to severe infection. Indeed, the phenomenon of parasitic sequestration is thought to have evolved primarily as an immune evasion strategy so the mature parasite can avoid passing through the spleen.[27]

Active erythrophagocytosis is a conspicuous feature within the bone marrow during *P. vivax* and *P. falciparum* malaria,[28,29] and it is highly probable that this also occurs within the spleen. Cytokines may be responsible for activating macrophages during malarial infection. Children with acute *P. falciparum* malaria have high circulating levels of interferon-γ (IFN-γ) and tumor necrosis factor-αTNF-α,[30] a synergistic combination of cytokines that activate macrophages.

Several studies have attempted to define the pathophysiologic changes in the spleen during acute malaria. In animal models, malaria is accompanied by increased intravascular clearance of infected or rigid, heat-treated cells by the spleen,[31] and alterations in the splenic microcirculation.[32] In studies of human malaria it has been found that increased splenic clearance of heated red cells occurs during acute attacks.[33] More recent, histologic studies and ex vivo models of splenic function suggest that the spleen removes not only mature infected red blood cells but also uninfected cells marked for clearance by low deformability, aggregated band 3, complement deposition, or phosphatidylserine exposure. Moreover, "pitting" of ring-stage infected cells may remove the parasite and leave the red cell marked with parasite antigen to return to the circulation (reviewed in Reference 34).

Changes to the uninfected red blood cells during infection also contribute to their own enhanced clearance by phagocytes. Uninfected red cells in children and adults with severe disease are less deformable, and this is a significant predictor of the severity of anemia and indeed outcome, consistent with the notion that these cells are being removed by the spleen.[20] It has also been found that immunoglobulin (Ig) G–sensitized red cells are rapidly removed from the circulation by the spleen and that unusually rapid clearance persists well into the convalescent phase.[35]

Thus all the available evidence points to increased reticuloendothelial clearance in *P. falciparum* malaria, persisting long after recovery. These changes are presumably a host defense mechanism, maximizing the clearance of parasitized erythrocytes.

The Role of Ineffective Erythropoiesis in Severe Malarial Anemia

Reticulocytopenia has been confirmed in numerous clinical studies of malarial anemia.[36-38] The histopathologic study of the bone marrow of children with malarial anemia shows erythroid hyperplasia with increased numbers of erythroid precursors (Fig. 160-4). However, the maturation is abnormal by light and electron microscopy. Abdalla et al[39,40] described the hallmark characteristics of such abnormal maturation, namely cytoplasmic and nuclear bridging and irregular nuclear outline. They later confirmed that the distribution of the erythroid progenitors through the cell cycle is abnormal in malarial anemia, with an increased proportion of cells in the G2 phase compared with normal controls.[41] Dormer et al[38] confirmed these findings using the same criteria as Abdalla et al; they studied six patients with falciparum malaria before and after treatment.

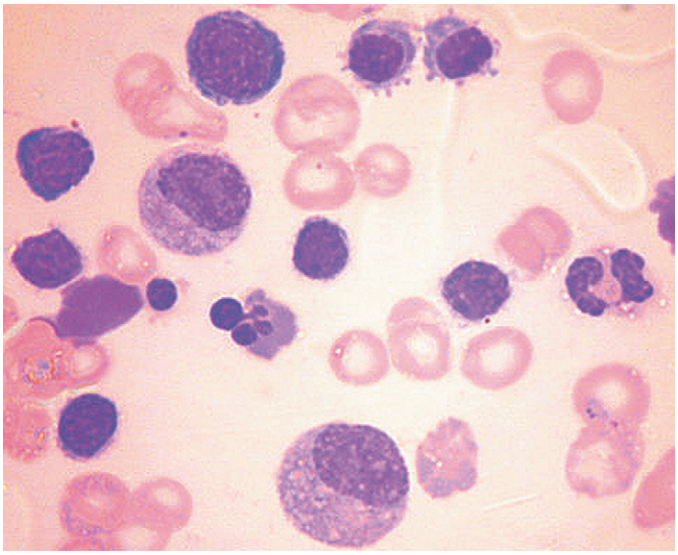

Figure 160-4 BONE MARROW ASPIRATE IN MALARIA. Although erythropoiesis is usually normoblastic in individuals with acute or chronic malaria, the examination of bone marrow frequently shows changes reflecting dyserythropoiesis, such as the irregular nuclei and cytoplasmic bridges in erythroblasts seen in this figure. Two young rings of *Plasmodium falciparum* can be seen in an erythrocyte. *(Courtesy Dr. Saad H. Abdalla.)*

Ineffective erythropoiesis also contributes to anemia in animal models of malaria. A recent study has shown that vaccinated *Aotus* monkeys, after a challenge infection, may develop moderate to severe anemia following rapid clearance of uninfected erythrocytes but with low reticulocyte counts, indicating bone marrow dysfunction.[42] Erythropoiesis is disrupted in mice during malarial infection. Mice infected with *Plasmodium berghei* show reduced bone marrow cellularity, erythroblasts, burst-forming units–erythroid (BFU-E), and colony-forming units–erythroid (CFU-E) as early as 24 hours postinfection.[43] The cellularity and colony-forming unit–spleen (CFU-S) content of the femoral marrow of BALB/c mice infected with *Plasmodium chabaudi adami* decreases as the parasitemia increases.[44]

Modulation of Erythropoiesis by Cytokines

Given the importance of erythropoietin (Epo) to erythropoiesis, attention has been focused on the levels of this crucial cytokine in malarial infection. Serum Epo was appropriately raised in a single study of African children suffering from malarial anemia.[45,46] However, other studies in adults from Thailand and Sudan have suggested that the Epo concentration, although raised, was inappropriate for the degree of anemia.[47,48] The most recent studies of the level of Epo in African children have shown a supraphysiologic rise in Epo levels compared to age-matched community controls with nonmalarial anemia.[49] There is now evidence that these high levels of Epo in children with malarial anemia may exert a cytoprotective effect and reduce the risk for neurologic sequelae or death in children with cerebral malaria.[50]

The prime candidates for the host factors mediating dyserythropoiesis are imbalances of TNF-α, IFN-γ, and interleukin-10 (IL-10). The concentrations of TNF-α and IFN-γ have been correlated with

the severity of the disease.[51-53] Whereas low concentrations of TNF-α (<1 ng/mL) stimulate erythropoiesis, higher levels of TNF-α have been shown to suppress erythropoiesis.[53] Furthermore, it is possible that high levels of these inflammatory cytokines may contribute to reduced and abnormal production of erythrocytes and also to increased erythrophagocytosis.

Recent evidence has suggested that the release of hepcidin is associated with malarial infection and that high levels of hepcidin could contribute to the sequestration of iron and impair erythropoiesis.[54,55] The stimulus for hepcidin secretion may be proinflammatory cytokines such as IL-6, but malaria-infected erythrocytes may also enhance hepcidin production by peripheral blood mononuclear cells.[56] Intriguingly, hepcidin released during blood-stage parasitemia may be a key regulator of *P. falciparum* liver-stage development.[57] This data now supports suggestions from large-scale studies of iron supplementation that iron may be at best useless and at worst harmful when given during acute malarial infection.

High levels of the Th2-type cytokine, IL-10, might prevent the development of severe malarial anemia. Low levels of IL-10 have been described in African children with severe malarial anemia.[51] Similarly, defective IL-12 production has been shown experimentally to be associated with increased severity of malaria in a rodent model, and low IL-12 levels have been associated with severe malaria in African children.[58,59]

Modulation of Erythropoiesis by Infected Erythrocytes

There is also substantial evidence that lysate of infected erythrocytes may directly modulate the function of host cells. During its blood stage, the malaria parasite proteolyses host hemoglobin in an acidic vacuole to obtain amino acids, releasing heme as a by-product, which is auto-oxidized to potentially toxic hematin (aquaferriprotoporphyrin IX, H_2O–Fe(III)PPIX). β-Hematin forms as a crystalline cyclic dimer of Fe(III)PPIX and is complexed with protein and lipid products as malarial pigment or hemozoin. Schwarzer et al[60-62] showed that the function of monocytes and of monocyte-derived macrophages is severely inhibited after ingestion of malaria pigment or hemozoin. These cells were unable to repeat phagocytosis and to generate oxidative burst when appropriately stimulated. Furthermore, after phagocytosis of hemozoin, human and murine myeloid cells were unable to kill ingested fungi, bacteria, and tumor cells[63] and to respond to IFN-γ stimulation, but instead responded by increased release of IL-1β and TNF-α,[64] macrophage inflammatory protein-1α (MIP-1α) and MIP-1β.[65]

The hemozoin polymer of heme moieties may be complexed with biologically active compounds. The oxidation of membrane lipids catalyzed by the ferric heme produces the lipoperoxides.[62,66] There is accumulating evidence that 4-hydroxynonenal (HNE) and other lipoperoxides, including 15-hydroxy-arachidonic acid (15-(*R*,*S*)-HETE), may play a role in the pathophysiology of malaria. It has been shown that HNE and HETE are generated in parasitized erythrocytes and that HNE and endoperoxides produced in pigment-containing monocytes or macrophages may cause cell cycle arrest and impair erythroid growth.[66,67] Hemozoin may also directly inhibit erythroid development in vitro and cause apoptosis of erythroid precursors. Furthermore, increased levels of plasma hemozoin and pigment in monocytes have been associated with anemia.[50,68]

Modulation of Erythropoiesis by Infection

In children presenting with acute malaria, bacteremia is associated not only with anemia but also with excess mortality.[69] Parvovirus B19 may cause a transient reticulocytopenia and thus severe and sudden anemia in those suffering from a hemolytic anemia or fetal anemia and intrauterine death. Most children in Africa have serologic evidence of infection early in life. However, acute infection with this virus is uncommon in those presenting with severe malarial anemia.[47,70]

Prevalence and Etiology of Anemia in the Developing World

In endemic areas the etiology of anemia is complex. Acute or chronic malarial infection is a major precipitating factor in children with severe anemia causing admission to hospital.[47]

Longitudinal studies from The Gambia have shown that whereas the mean hemoglobin levels in children vary significantly through the year, anemia is much more common in the rainy season, when malaria transmission is at its highest.[71] However, the rains are also associated with an increase in water-borne diarrheal disease and poor food supplies. So the seasonal increase in anemia in malaria-endemic areas arises on a background of low or frankly deficient stores of hematinics and/or other micronutrients. Iron deficiency, which affects at least 20% of the world's population, is a major factor in the seasonal surge of anemia in the tropical rainy season. Low iron stores at birth and dietary iron deficiency may be exacerbated by hookworm or schistosomal infection. It is now also clear that malarial infection is associated with reduced uptake of available iron and reduced incorporation of iron into developing erythroid cells.[54,55] Folate deficiencies and/or increased requirements may occur in many populations, although frank folate deficiency is uncommon.

A low baseline hemoglobin level at the start of the season for malaria transmission is a major risk factor for developing severe malarial anemia and has encouraged studies aimed at preventing the development of anemia by hematinic supplementation with or without antimalarial prophylaxis or surveillance.[72]

Quantifying the contribution of these individual factors to anemia reliably requires intervention studies. In Tanzania, Menendez et al[73] and Schellenberg et al[74] have shown that iron supplementation and antimalarial prophylaxis prevented 30% and 60%, respectively, of all cases of moderate anemia presenting during the malaria transmission season in children and in infants.

Translating the results of these studies from well-defined and carefully controlled study areas has not been easy. Considerable concerns about iron supplementation programs for children have been raised in sub-Saharan Africa and in areas of high malaria endemicity. One large trial of iron supplementation was stopped because of increased hospital admission and death in the group receiving iron. However, metaanalysis of iron supplementation in malaria-endemic areas has shown that iron alone or with antimalarial treatment does not increase the risk for clinical malaria or death when regular malaria surveillance and treatment services are provided.[75] It is increasingly clear that iron supplementation in these areas must be based on either defining iron-deficient children or combining iron administration with effective infection control and treatment strategies.[76]

Features of Malarial Anemia

The Spectrum of Disease Caused by Malarial Infection

The signs and symptoms of malarial infection in humans are caused by the asexual blood stage of the parasite. Infection with blood-stage parasites may result in a wide range of outcomes and pathologic conditions. Indeed, the spectrum of severity ranges from asymptomatic infection to rapidly progressive, fatal illness. The clinical presentation of malarial infection is also wide and influenced by age, immune status, and pregnancy and by the species, genotype, and perhaps the geographic origin of the parasite. In endemic areas, many infections present as an uncomplicated febrile illness. In more severe forms of the disease, children may present with prostration or inability to take oral fluids or in younger children an inability to suckle. Alternatively, they may exhibit a number of syndromes of severe disease, including anemia, coma, respiratory distress, and hypoglycemia and may also have a high rate of bacteremia.[69,77]

In most age-groups, anemia is frequently accompanied by more than one syndrome of severe disease, and the already substantial case

fatality rate of 15% to 20% for severe malaria in African children rises significantly when multiple syndromes of severe disease are present.[77]

The age distribution of anemia and other syndromes of severe disease is a consistent but puzzling feature of the epidemiology of clinical malaria. Children born in endemic areas are protected from severe malaria in the first 6 months of life by the passive transfer of maternal immunoglobulins and by fetal hemoglobin. Beyond infancy, the most common form of presentation of severe disease changes from anemia in children ages 1 to 3 years old, in areas of high transmission, to cerebral malaria in older children, in areas of lower transmission.[78] As transmission intensity declines further, severe malaria is most frequently found in older age-groups.

The Clinical Features of Malarial Anemia

The blood stage of falciparum malaria may cause life-threatening anemia; a hemoglobin level of less than 5 g/dL is considered to represent severe disease. Children with anemia may present with malaise, fatigue, and dyspnea or respiratory distress, which usually represents metabolic acidosis, but in an ill child acute respiratory infection must be carefully excluded.[77,79]

Acidosis is largely due to excessive lactic acid and other anions. Salicylate toxicity and dehydration may also play a role. However, the majority of children presenting with respiratory distress are severely anemic, have a metabolic acidosis secondary to reduced oxygen-carrying capacity, and respond to rapid transfusion of fresh blood (for review see reference 80). A minority of those with respiratory distress do not respond to appropriate resuscitation. They probably represent a heterogeneous clinical group and may have renal failure, systemic bacterial infection, or a more profound syndrome of systemic disturbance due to malarial parasites.

However, a large randomized trial of a bolus of fluids in the treatment of African children with shock and life-threatening infections showed somewhat surprisingly that fluid boluses significantly increased 48-hour mortality in these critically ill children with impaired perfusion.[81] Fluid resuscitation must be carefully supervised.

Hemolytic Syndromes, Including Blackwater Fever

The sudden appearance of hemoglobin in the urine, indicating severe intravascular hemolysis leading to hemoglobinemia and hemoglobinuria or blackwater fever, received particular attention in early studies of anemia in expatriates living in endemic areas.[82] There was an association between blackwater fever and the irregular use of quinine for chemoprophylaxis. This drug can act as a hapten and stimulate production of a drug-dependent complement-fixing antibody. Recent studies of sudden intravascular hemolysis have shown that it is rare in Africa but more common in Southeast Asia and Papua New Guinea, where some cases are associated with G6PD deficiency and treatment with variety of drugs, including quinine, mefloquine, and artesunate.[83] However, in the majority of cases, the cause of sudden hemolysis cannot be accounted for, and it seems likely that unidentified hemolytic mechanism(s) may operate.

The Hematologic Features of Malarial Infection

The anemia of falciparum malaria is typically normocytic and normochromic, with a notable absence of reticulocytes, although microcytosis and hypochromia may be present because of the very high frequency of α- and β-thalassemia traits and/or iron deficiency in many endemic areas.[47,71]

The anemia of malaria may be accompanied by changes in the white cell and platelet counts and in clotting parameters, but these changes are not in themselves diagnostic nor do they guide management. Malaria is accompanied by a modest leukocytosis, although leukopenia may also occur. Occasionally leukemoid reactions have been observed. Leukocytosis has been associated with severe disease.[84,85] A high neutrophil count may also suggest intercurrent bacterial infection. Monocytosis and increased numbers of circulating lymphocytes are also seen in acute infection, although the significance of these changes is not established.[86] However, malarial pigment is often seen in neutrophils and in monocytes and has been associated with severe disease and unfavorable outcome.[87,88]

Thrombocytopenia is almost invariable in malaria and so may be helpful as a sensitive, but nonspecific, marker of active infection. However, severe thrombocytopenia (platelet count $<50 \times 10^9$/L) is rare. Increased removal of platelets may follow absorption of immune complexes or platelet activation, but there is no evidence for platelet-specific alloantibodies.[89] By analogy with erythropoiesis, there may be a defect in thrombopoiesis but this has not been established. Thrombocytopenia is not associated with disease severity, although somewhat paradoxically platelets have been shown to contribute to disease pathology in animal and in human malaria.[90,91] Moreover, in human infections, platelets may form clumps with infected erythrocytes.[92] One explanation of this paradox could be that low levels of platelets might not only be a marker of parasite burden but also be protective from severe disease and/or be associated with antiinflammatory cytokine responses.[93]

Disordered coagulation and clinical evidence of bleeding are not infrequent in nonimmune adults contracting malaria and presenting with severe disease. Patients may present with bleeding at injection sites, gums, or epistaxis. Abnormal test results for laboratory tests of hemostasis, suggesting activation of the coagulation cascade, occur in acute infection. However, histologic evidence of intravascular fibrin deposition is notably absent in adults dying from severe malaria.[94] Factor XIII, normally responsible for cross-linking fibrin, is inactivated during malarial infection, and these data may explain low levels of fibrin deposition in the face of increased procoagulant activity.[95]

During acute disease the levels of a disintegrin and metalloproteinase with thrombospondin motifs 13 (ADAMST13) protease are moderately reduced, and the concentration of high-molecular-weight von Willebrand multimers is increased. Such multimers may play a role in the adherence of infected red blood cells and platelets to endothelium, but the role of this adhesive pathway in the etiology of severe and cerebral malaria has not been established.[96]

The bone marrow is typically hypercellular. The most striking findings are of grossly abnormal development of erythroid precursors or dyserythropoiesis. The developing erythroid cells typically demonstrate cytoplasmic and nuclear bridging and irregular nuclear outline.[39,40] These changes are probably central to the pathophysiology of malarial anemia and are discussed in detail later. The proportion of abnormal erythroid precursors and the degree of dyserythropoiesis are markedly greater in chronic compared to acute infection, suggesting that the inhibition and abnormal maturation of erythroid precursors may have somewhat differing etiologies in acute and chronic infection.[39]

The role of hematinic deficiency in children presenting with malaria and anemia may be difficult to assess. The relative importance of absolute and functional iron deficiency have not been defined. Iron will not be absorbed during acute infection because hepcidin levels are raised.[54,55] Nevertheless, many hospitals give a course of iron supplementation after an episode of acute malaria, although no general guidelines have been established. Chronic hemolysis may increase folate requirements, but frank deficiency is uncommon in children presenting with acute malaria, at least in East Africa.[47] Folate deficiency may be more common in West Africa, and protocols for folate supplementation after malaria must reflect local experience.

Malarial Anemia in Pregnancy

Pregnancy is accompanied by a series of physiologic changes that predispose not only to anemia but also to malaria. Hemodilution causes a physiologic decrease in hemoglobin. Moreover, the demand

for both iron and folate increases as the fetus grows and often precipitates frank folate or iron deficiency, particularly in multigravid women.

Occult malarial infection, often without fever, may cause anemia and placental dysfunction. This effect is greatest in primigravidas and has been attributed to the adhesion of parasitized erythrocytes to chondroitin sulfate A and hyaluronic acid in the placenta[97,98] (for review see reference 99). Fetal growth is impaired, and babies born to women with placental malaria are on average 100 g lighter than controls born to women without malaria. The subsequent contribution of malaria to infant mortality is substantial.[100] Furthermore, the increase in hematopoiesis demanded by hemolysis during malarial infection may precipitate frank folate deficiency. Finally, women who are not immune to malaria are more likely to develop hypoglycemia and pulmonary edema during pregnancy.

The increase in maternal and fetal morbidity and mortality secondary to malaria may be prevented by routine hematinic supplementation and by intermittent treatment with antimalarials during the second and third trimesters with sulphadoxine-pyrimethamine (Fansidar).[101]

Hyperreactive Malarial Splenomegaly

Although splenomegaly secondary to malarial infection usually regresses as immunity is acquired, some people living in endemic areas develop progressive, massive splenomegaly.[102] The pathophysiology of such hyperreactive malarial splenomegaly (HMS) is poorly understood but certainly results in B-cell hyperplasia with high levels of polyclonal IgM, reaching a level greater than 2 standard deviations (SDs) above the local reference mean. The specific antimalarial antibody titer is high, although only a small proportion of the polyclonal IgM response is directed at malarial antigens. B-cell hyperplasia may provoke proliferation of both T cells and macrophages, and IgM levels may cause cryoglobulinemia and stimulate erythrophagocytosis.

Patients may present typically between 20 and 40 years old, with massive splenomegaly without lymphadenopathy, anemia that may be severe, neutropenia, and thrombocytopenia. The anemia may cause life-threatening hemolytic crises and/or neutropenia associated with severe bacterial infection. Thrombocytopenia is rarely symptomatic. The bone marrow shows hypercellularity, with a lymphocytosis in marrow and peripheral blood. The high IgM levels distinguish HMS from chronic lymphocytic leukemia or other lymphoproliferative disorders. However, the polyclonal proliferation of B cells may transform to a true clonal lymphoproliferative disorder. This appears to be derived from a naive B cell, although the exact classification of such lymphoproliferative disorders is poorly defined[103]; however, there is a single report of a high incidence of B prolymphocytic leukemia in one population.

Treatment for HMS is lifelong antimalarial prophylaxis. Signs and symptoms usually subside over 1 to 2 years, but relapse may occur if antimalarial therapy ceases. Splenectomy is contraindicated because it is technically difficult, with considerable interoperative mortality and may predispose to severe infection.

Anemia and *P. vivax, P. ovale,* and *P. malariae* Infection

In *P. vivax* and *P. ovale* malaria, high parasitemias are rare because invasion of erythrocytes is limited to reticulocytes. However, there is an emerging consensus that *P. vivax* monoinfection may cause severe disease with cerebral malaria and/or anemia (for review see reference 104). The vivax-infected red blood cell can adhere to host cells, but sequestration in the peripheral circulation and organ-specific syndromes of disease are much less common than in falciparum malaria.

P. vivax malaria has been associated with anemia during pregnancy and with low birth weight of children of affected mothers. Here cytokines or other inflammatory mediators appear to cause placental dysfunction.[105] *P. malariae* infection is also rarely fatal but is distinguished by the persistence of blood-stage parasites for up to 40 years. It can, however, cause a progressive and fatal nephrotic syndrome.[106]

Malaria Diagnosis

The diagnosis of malaria is based on the identification of circulating blood-stage parasites. The standard methods of preparing thick and thin films are straightforward and allow a simple method to diagnose infection (Table 160-1).[107-109] However, malaria diagnosis poses particular problems for inexperienced staff. The main biologic problem is that the level of circulating parasites is only weakly associated with the overall parasite burden because falciparum-infected erythrocytes are sequestered in capillary venules; thus the parasitemia is not a reliable guide to the severity of disease. Second, missing or delaying the diagnosis of falciparum malaria may result in serious morbidity and mortality. Finally, the most sensitive methods for diagnosis of infection, namely microscopy, require both skill and time.

In endemic areas, laboratory staff are skilled at the examination of thick films and routinely are able to detect 1 parasite in 100 high-power fields of a thick film, which corresponds to a sensitivity of approximately 5 to 50 parasites/μL.[107,110] Thin films are used for determining the species of the parasites, and the circulating asexual forms of the four main malaria species can be readily identified, whereas the sexual forms (gametocytes) of the species require some skill and regular practice (Figs. 160-5 and 160-6).

Nevertheless, diagnosis of malaria by microscopy in nonendemic countries has proven problematic. Routine laboratories may only achieve sensitivities of the order of 500 parasites/μL using thick films.[110,111] Quality assurance schemes show that performance of routine hematology laboratories in the recognition of and species determination of malaria parasites is poor.[109,111]

There has therefore been a strong drive to use nonmicroscopy methods for malaria diagnosis. It is now apparent that these methods are not sufficiently sensitive for clinical diagnosis, although they may have a role in detecting parasites of more than 500 parasites/μL when experienced staff are not available and/or as part of an out-of-hours service. However, it must be emphasized that these tests are no substitute for careful microscopy. Operationally this means that hematology laboratories need to make the diagnosis of malaria and must maintain the skills needed for reliable examination of thick films.

Table 160-1 Malaria Diagnosis

Thick and thin films should be prepared for cases of suspected malaria.
Immunochromographic tests lack sensitivity to detect low levels of parasites that may be highly clinically significant.
Routine Giemsa or May-Grünwald-Giemsa stains are unlikely to give satisfactory results because the pH is too low.
Films can be stained with Giemsa or Leishman stain (thin films) or Field stain (thick films). (For details see *Guideline: The Laboratory Diagnosis of Malaria,* www.bcshguidelines.org.)
Two hundred high-power fields (×100 objectives) should be examined in a thick film.
Asexual parasitemia should be reported after counting 1000 RBCs in a thin film. A graticule or grid may help counting.
If parasitemia is less than 1 : 1000 RBCs, parasitemia may be counted in a thick film in relation to the number of WBCs.
During active infection, daily parasite count should be obtained.
Counting and species determination of malaria parasites should be verified by a second observer.
Reports on negative films despite a strong clinical suspicion of malaria should be qualified that negative films do not exclude a diagnosis of malaria. Repeat films should be requested if clinically appropriate. Thrombocytopenia may heighten suspicion of malaria.

RBC, Red blood cell; *WBC,* white blood cell.

A number of methods based on the fluorescent staining of parasite deoxyribonucleic acid (DNA) and/or ribonucleic acid (RNA) and the concentration of parasites have been devised.[112-114] However attractive these methods may appear, their sensitivity is limited by background staining of cellular debris, and the limit of their sensitivity is approximately 100 parasites/μL. The time taken in preparing samples and the specialized equipment and skills needed to use these methods limit their effectiveness in routine practice.

Detection of circulating malarial antigens is another potentially attractive, but ultimately limited, alternative to the laborious method of screening blood films. The widely available tests detect *Plasmodium* histidine-rich protein 2 (BinaxNow malaria test) and *Plasmodium*-specific lactate dehydrogenase (OptiMal-IT test) by immunochromatography.[115] The formulation of the tests using dipstick antigens allows rapid testing to be performed by laboratory staff. However, the sensitivity is 100 to 1000 parasites/μL, and this is comparable to the sensitivity achieved by inexperienced but not experienced microscopists. The current recommendations for malaria diagnosis in the United Kingdom emphasize clearly that these tests only have a place when experienced staff are not available or to provide a rapid diagnosis that will be later confirmed by microscopy to exclude low-level infection and/or determine the species and quantify the infection.[116]

Amplification of circulating parasite DNA using the repeated ribosomal RNA (rRNA) genes is an extremely sensitive method of malaria diagnosis.[117] The sensitivity may be as low as 0.005 parasites/μL or 5 parasites/mL.[118,119] Undoubtedly, this is a useful tool for reference laboratories but is not yet in routine diagnostic use.

Treatment

Malaria requires urgent effective chemotherapy to prevent progression of disease and may be the most crucial public health intervention to reduce global mortality from malaria. The drug treatment of malaria must take account of the expected pattern of drug resistance in the area where infection was contracted, the severity of clinical disease, and the species of parasite. The spread of drug-resistant parasites and the optimal use of affordable, effective drugs are of continual concern, and these have recently been reviewed (Table 160-2).[116,120,121] Artemisinin-based combination treatments have been the mainstay of treatment for falciparum malaria in Southeast Asia for more than 10 years and are now recommended as first-line treatment throughout the rest of the world.[122] The hematologic side effects of antimalarial drugs in use today are few. Amodiaquine is associated with neutropenia and agranulocytosis. Artemisinin-based treatments may cause reticulocytopenia, but this is not clinically significant.

In severely ill patients, good nursing care is vital. Monitoring and treatment of fits and hypoglycemia is essential, and antipyretics should be given.[123]

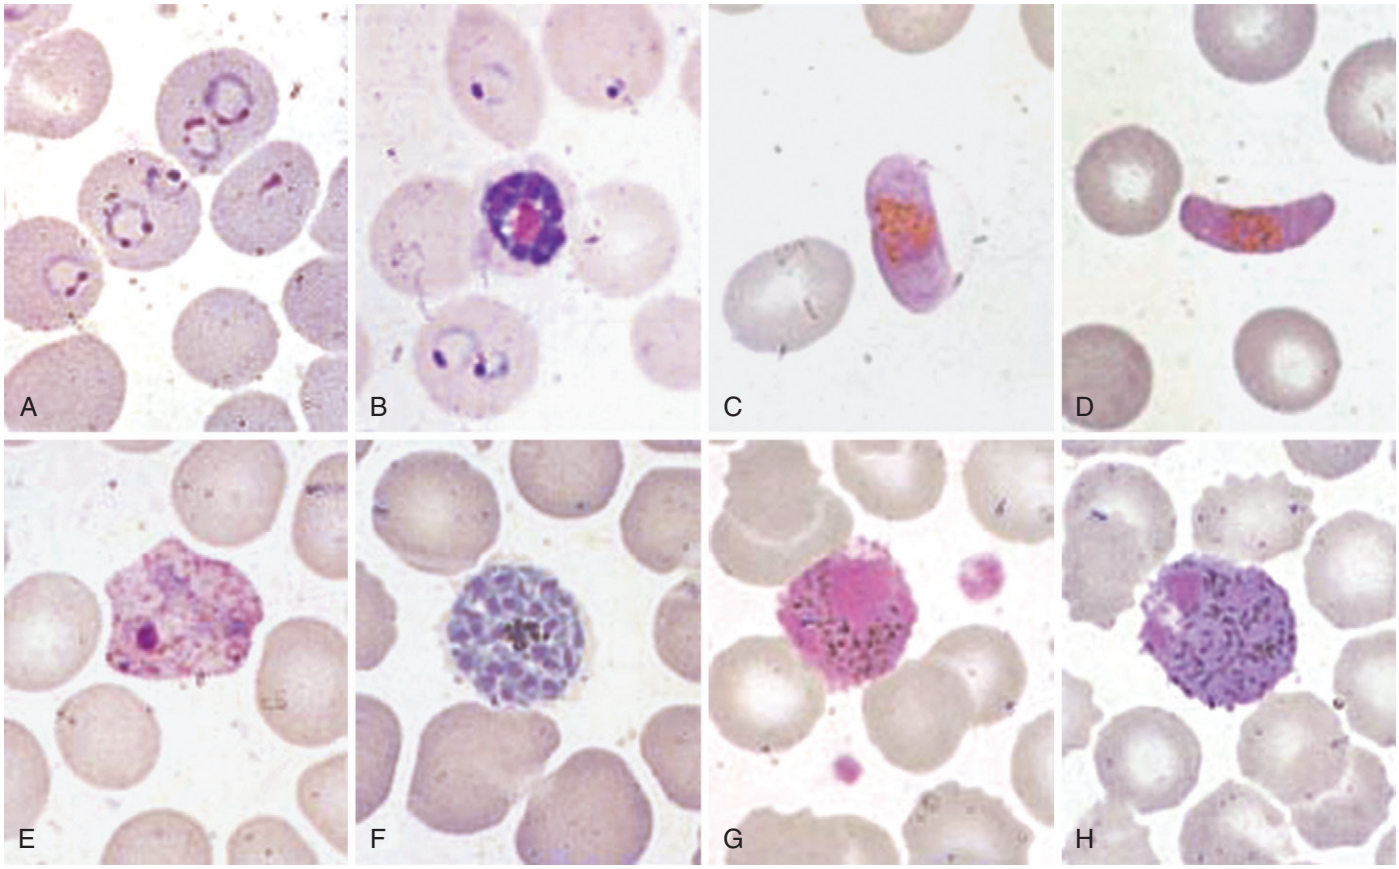

Figure 160-5 BLOOD STAGE MALARIA (THIN BLOOD FILMS). *Plasmodium falciparum:* Fine rings **(A)** predominate, with mature trophozoites and schizonts **(B)** appearing uncommonly in the peripheral circulation because infected cells adhere to postcapillary venules. Host cells are not enlarged. Basophilic clefts and spots of irregular shape and size (Maurer clefts and dots) may be seen in erythrocytes containing more mature parasites. They are thought to be aggregates of parasite proteins that are being exported from the parasite to the surface of the red cell. Crescent-shaped male **(C)** and female gametocytes **(D)** are diagnostic. *Plasmodium vivax:* All stages of asexual parasites—from young trophozoites **(E)** to schizonts—appear in the peripheral circulation in vivax malaria together with gametocytes. The parasites are large and ameboid and produce schizonts with approximately 16 daughter cells (merozoites) **(F)**. Pigment is well developed. Host red cells are enlarged and uniformly covered with fine eosinophilic stippling (Schüffner dots). Gametocytes are round, with the male (microgametocytes; **G**) being approximately 7 μm and the female (macrogametocytes; **H**) being 10 μm or more in diameter.

Continued

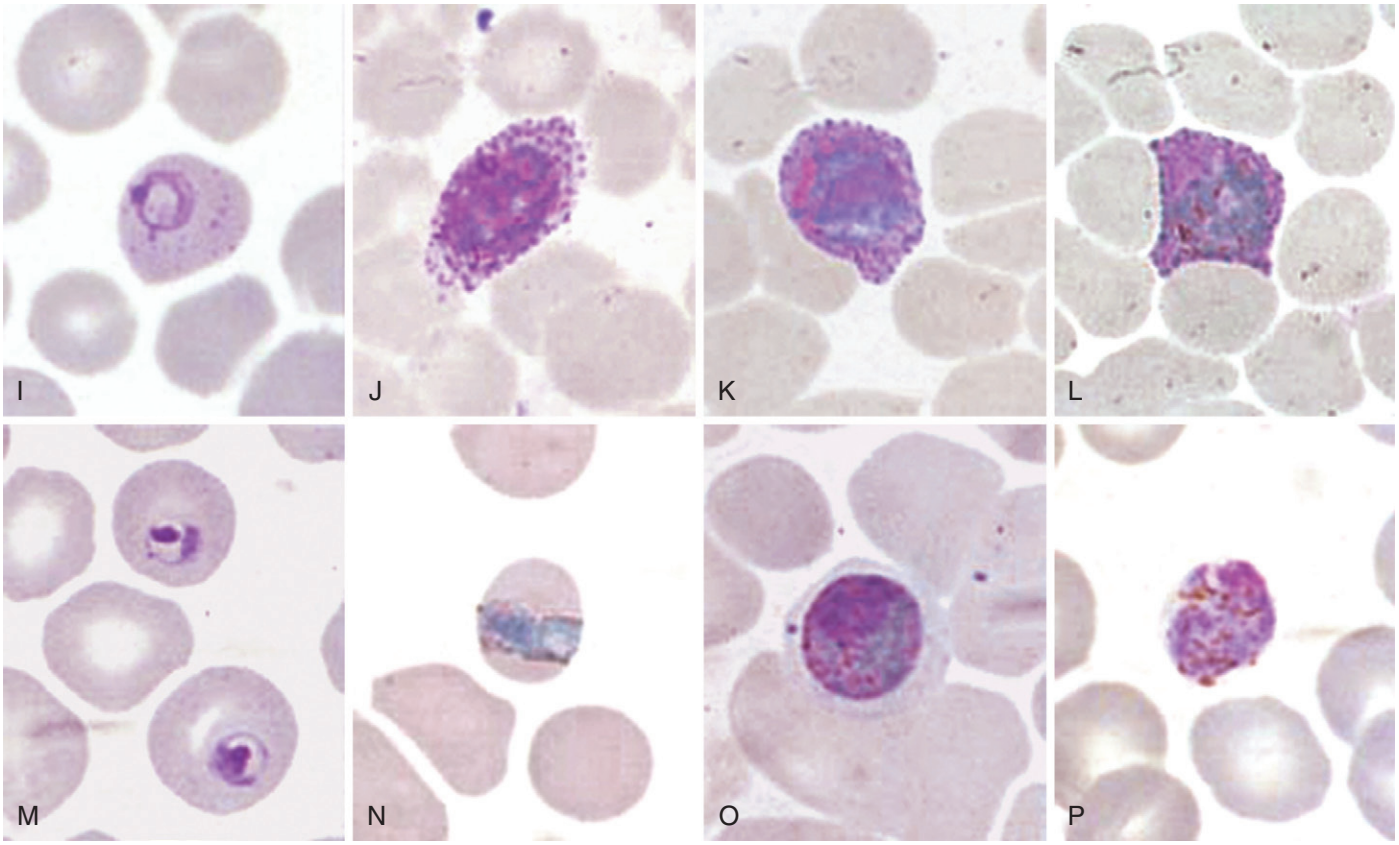

Figure 160-5, cont'd *Plasmodium ovale:* Intraerythrocytic ring forms **(I)** have a prominent nucleus. The older parasites (**J**) differ from *P. vivax* in being more compact and producing about eight merozoites at schizogony. Like *P. vivax*, the host red cells contain Schüffner dots and tend to be ovoid and fimbriated. Male (microgametocytes) and female (macrogametocytes) gametocytes (**K** and **L**) are smaller than those of *P. vivax. Plasmodium malariae:* All intraerythrocytic stages may appear in the peripheral circulation, from young trophozoites **(M)** to compact schizonts with eight merozoites. Band forms **(N)** stretching across the red cell are common. With special staining, a very fine stippling (Ziemann dots) is sometimes seen. Host red cells are not enlarged. Gametocytes, no larger than their host cells, are round and compact with distinct blackish pigment, being finer in the males **(O)**, in which the nucleus is more diffuse and the cytoplasm somewhat mauvish, whereas the granules are fewer and larger in the female **(P)**, which stains a bluer color.

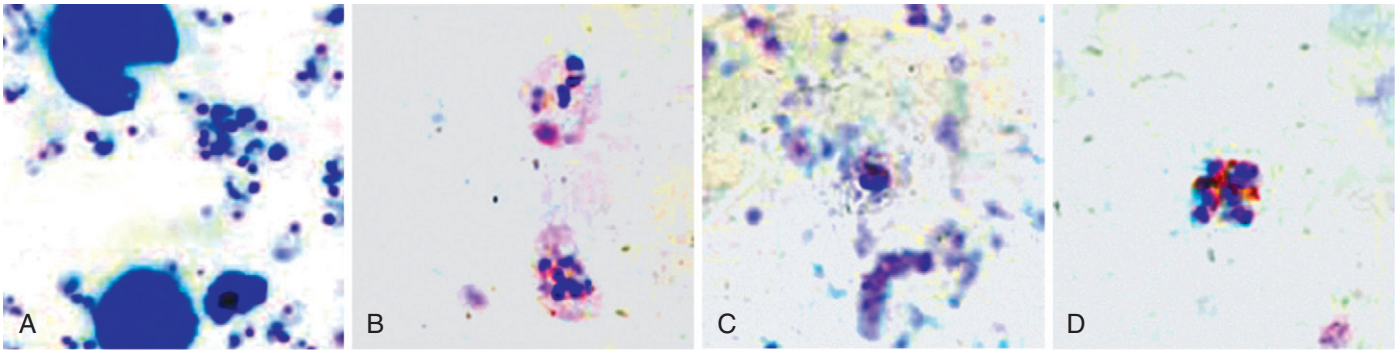

Figure 160-6 BLOOD-STAGE MALARIA (THICK BLOOD FILMS). *Plasmodium falciparum:* Usually only young rings **(A)** are seen in acute infections, although sometimes in very large numbers. *Plasmodium vivax:* All stages may be present; here two young trophozoites are seen **(B)**, with Schüffner dots seen as "ghost cells" in the thinner parts of the film where the host cell has been hemolyzed. *Plasmodium ovale:* The Schüffner dots of *P. ovale* also may show up in a thick film as a ghost cell, but the parasite can be distinguished from *P. vivax* by the solid appearance and heavy pigment even of young trophozoites **(C)**. *Plasmodium malariae:* Younger parasites can be recognized by their heavy pigment, but this may be so heavy that it obscures the other inner structures. Schizonts containing up to eight merozoites with a central mass of pigment **(D)** are characteristic. *P. malariae* is difficult to differentiate from *P. ovale* in thick films, in which the parasites are easily confused. However, unlike *P. malariae, P. ovale* may be seen in ghost cells **(C)**.

Certainly, blood transfusion is in principle a straightforward solution to the treatment of severe malarial anemia, although controversy exists over the trigger for transfusion and the rate of administration of blood. The standard regimens of cautious and slow delivery of blood have been challenged by the demonstration that rapid initial flow rates may correct lactic acidosis and hypovolemia. However, in nonimmune patients and in pregnant women, blood transfusion must be accompanied by careful hemodynamic monitoring to avoid precipitating or exacerbating pulmonary edema.

No formal controlled trials for the transfusion of patients with malaria have been performed. Whatever clinical guidelines emerge, in reality blood transfusion in the heartland of malaria-endemic areas

Table 160-2 Commonly Used Antimalarial Drugs and Their Side Effects

	Oral Dose	Parenteral Dose	Side Effects
Sulphadoxine-pyrimethamine	Sulphadoxine 25 mg/kg Pyrimethamine 1.25 mg/kg as a single dose (max 1500 mg sulphadoxine and 75 mg pyrimethamine)	For IM injection, doses as for oral	Use with caution in first trimester Causes kernicterus in neonates Skin rashes, fatal Stevens-Johnson syndrome
Artemether	3.2 mg/kg day 1 1.6 mg/kg days 2-7	3.2 mg/kg IM day 1, then 1.6 mg/kg for 3 days, then oral	Reticuolcytopenia
Artesunate	4 mg/kg OD for 7 days	2.4 mg/kg IM day 1, then 1.2 mg/kg for 3 days, then oral	Reticulocytopenia
Artemether/lumofantrine	Fixed-dose combination: artemether (20 mg) with lumofantrine (120 mg), adults give 4 tablets initially, followed by 5 further doses of 4 tablets each given at 8, 24, 36, 48, and 60 hours (total 24 tablets over 60 hours) If 5-15 kg, then 1 tablet initially followed by 5 further doses of 1 tablet each, given at 8, 24, 36, 48, and 60 hours (total 6 tablets over 60 hours); 15-25 kg, then 2 tablets initially, followed by 5 further doses of 2 tablets each given at 8, 24, 36, 48, and 60 hours (total 12 tablets over 60 hours); bodyweight 25-35 kg, 3 tablets initially, followed by 5 further doses of 3 tablets each given at 8, 24, 36, 48, and 60 hours (total 18 tablets over 60 hours)		
Quinine	10 mg/kg of salt (max 600 mg) 8 hourly for 7 days, together with or followed by either doxycycline 200 mg once daily for 7 days or clindamycin 450 mg every 8 hours for 7 days [unlicensed indication]	20 mg/kg in 10 mL/kg isotonic fluid over 4 hours, then 10 mg/kg over 2 hours given 12 hourly in children and 8 hourly in adults, together with or followed by either doxycycline 200 mg once daily for 7 days or clindamycin 450 mg every 8 hours for 7 days [unlicensed indication]	Thrombocytopenia, intravascular hemolysis (blackwater fever) when used prophylactically, nausea, tinnitus, deafness

IM, Intramuscular; *max,* maximum; *OD,* once a day.

is beset by many practical and theoretic problems. First, the absence of well-characterized donor panels (and thus systematic blood collection) frequently jeopardizes the supply of blood. Second, even when standard screening for HIV is in place, the residual risk for human immunodeficiency virus (HIV) transmission in the serologic window of infectivity remains at 1 in 2000.[124] At a practical level, positive indirect antiglobulin tests in acute infection may make the exclusion of alloantibodies difficult. Depending on the clinical urgency and transfusion history, the least serologically incompatible blood may have to be given.

One therapeutic option available in North America and in Europe for the urgent treatment of nonimmune patients with severe disease would be an exchange blood transfusion. This procedure removes nonsequestered, infected erythrocytes and possibly circulating toxins. In the absence of evidence from trials for the use of exchange transfusion in malaria, some have suggested that this treatment could be given for hyperparasitemia (>20%) in severely ill nonimmune patients.[125,126]

The salient features that make this clinical problem a major public health concern are the very large numbers of children affected and the difficulty of satisfactory treatment by blood transfusion outside specialist centers.

Malaria as a Transfusion-Transmitted Infection

Malaria is undoubtedly the most common transfusion-transmitted infection in the world. In endemic areas a large proportion of adult donors will be parasitemic, perhaps 20% to 80%, depending on the rate of transmission. Here donor deferral is impractical, and treatment of recipients with a course of effective antimalarials is the most practical alternative.

In nonendemic areas, transmission of malaria is an occasional but potentially devastating complication of blood transfusion, and considerable thought and resources are required to combat the problem effectively.

The first case of transfusion-transmitted malaria (TTM) was in 1911.[127] Between 1911 and the mid-1970s the incidence of TTM rose to more than 140 cases per year, with *P. vivax* the most common species causing infection, although the proportion of cases due to *P. falciparum* has steadily increased, perhaps reflecting the speed and destination of international travel. It is striking that the background problem, namely, malaria in returned travelers, is much more common in the United Kingdom than the United States, with the per capita incidence differing by nearly a factor of 10 and a higher proportion of cases due to *P. falciparum* in Europe and the United Kingdom compared with the United States.[128]

Recent experience in the United Kingdom and the United States has emphasized the seriousness of TTM. Two of the last five cases of malaria due to blood transfusion in the United Kingdom were fatal.[129-131] In the United States, 14 cases of TTM were reported between 1990 and 1999, but only 5 cases between 2000 and 2009.[132,133]

Detecting these cases after transfusion is frequently delayed because malarial infection acquired in nonendemic countries rarely figures in immediate differential diagnosis and requires careful examination of the blood film.

The mainstay of preventing TTM in the United Kingdom is donor deferral backed up by detection of circulating antibodies to

Table 160-3 UK Donor Selection Guidelines for Donors "At-Risk" of Transmitting Malaria

Donor "Risk" Category	Guidelines
Resident	Defined as having lived in sub-Saharan Africa (except South Africa) or Papua New Guinea for a continuous period of 6 months at any time of life Permanent deferral unless malaria antibody test results are negative at least 6 months after returning from a malarious area Any subsequent visits to any malarious area each require a 6-month deferral period and negative antibody test results before reinstatement
History of malaria	Permanent deferral unless malarial antibody test results are negative at least 3 years after cessation of treatment or last negative test results
Undiagnosed febrile illness	While abroad or within 4 weeks of return Deferral for 12 months or 6 months if malarial antibody test results are negative
All other risks	Deferral for 12 months or 6 months if malarial antibody test results are negative

malaria antigens. The guidelines for donor deferral were carefully revised after analysis of circumstances of recent TTM (Table 160-3).[134] These criteria recognize that malaria in the nonimmune patient is likely to present within 6 months of return from an endemic area and that significant immunity to falciparum malaria may be acquired by residence after 6 months in a malarious area.

The criteria also required that residents, those having had malaria or an undiagnosed febrile illness, may be reinstated if antimalarial antibodies cannot be detected. The importance of antimalarial antibody testing rests on the fact that it is a very sensitive method to detect chronic infection, whereas the identification of circulating malarial antigens or nucleic acids or microscopy would fail to detect a level of 1 parasite/mL, which would still give a highly infectious dose in a unit of blood.

The assays for antimalarial antibodies previously used indirect immunofluorescence antibody tests (IFATs) to detect reactivity to a crude parasite lysate as a target antigen. However, an enzyme-linked immunosorbent assay (ELISA) using recombinant malarial antigens has proved to be a more practical if slightly less sensitive alternative to IFAT.[131,134,135] These tests detect antimalarial antibodies in less than 2% of donors who have visited endemic areas. It has been calculated that the return of 90% of malarial antibody–positive visitors to the donor pool releases an extra 50,000 units a year in the United Kingdom, and this is a highly cost-effective process to reduce the attrition of eligible blood donors. In the United States, over 200,000 donors a year are deferred after travel to malaria-endemic areas.

Donor deferral is based on the potential of a donor to carry malaria and is therefore based on the area of travel, length of stay or residence, elapsed time since leaving the endemic area, and history of malaria. It has been repeatedly shown that application of even the most thorough donor questionnaires allows some of those carrying malaria to give blood because guidelines are frequently incorrectly applied or questions answered inaccurately in routine practice.[133,136]

In Canada donors reporting diagnosis or treatment of malaria defer permanently, and in the United States donors are deferred for 3 years after treatment.[133] The criteria will inevitably cause unnecessary deferral of those who never actually had malaria but also permits some individuals with low-level chronic infection to donate because malaria not infrequently presents more than 3 years after returning from endemic areas.[133,132] The last case of malaria transmitted in the United Kingdom was by someone who left a malarious area 8 years previously, and the longest recorded case of recrudescence of malarial infection is 44 years for *P. malariae*.

In conclusion, permanent deferral of all those visiting malaria-endemic areas is unlikely to be a viable strategy to prevent TTM because donor bases are declining. Preventing malaria transmission through blood transfusion requires comprehensive, regularly reviewed, and effectively implemented guidelines for donor deferral and laboratory testing. Even the best strategy is a compromise, and medical laboratory staff should be aware of the rarely, but potentially serious, possibility of fever after transfusion that could be caused by malaria.

VISCERAL LEISHMANIASIS

Leishmaniasis is a generic term of infection by 30 or so species of the obligate intracellular parasites from the genus *Leishmania*. Visceral leishmaniasis (VL), or kala-azar, presents with a wide spectrum of systemic and hematologic features.

Epidemiology

VL occurs in all countries bordering the Mediterranean and across the Middle East, including Saudi Arabia and Yemen. Indian VL occurs in the eastern regions (particularly Assam, Bengal, Bihar, Uttar Pradesh, Madras, and Sikkim) and in Nepal and Bangladesh. African kala-azar is endemic in Kenya, Ethiopia, and the Sudan and sporadically elsewhere in tropical Africa. In the Americas, VL occurs in foci across Mexico, Central America, Colombia, Venezuela, Guyana, Brazil, Bolivia, and northern Argentina (Fig. 160-7).

The total burden of disease is difficult to estimate but significant. Leishmaniasis burden is endemic in 88 countries, with 500,000 new cases of VL per year, with the vast majority occurring in India, Bangladesh, Nepal, Northern Sudan, and northeastern Brazil.[137] VL is associated with poverty and undernutrition in endemic areas, particularly in the hyperendemic foci of southern Sudan and the Ganges river basin. In the Mediterranean area, it is increasingly seen in association with HIV infection, where infection rates in HIV-infected people may be as high as 10%.

VL is caused by a number of species of the *Leishmania donovani* complex.[138,139] In the Mediterranean and areas in the Middle East and Central Asia through to China, *Leishmania infantum* predominates, whereas *L. donovani* is more prevalent in India. *Leishmania tropica* is a less common cause of VL in these areas. Throughout their range in the Old World, parasites are transmitted by the female sandfly of the *Phlebotomus* genus.

Leishmaniasis is caused by different parasites and vectors in the New World, where *Leishmania chagasi* and *Leishmania amazonensis* are transmitted by the *Lutzomyia* genus of sandfly.

Leishmania organisms are present in blood, and so the disease can be transmitted by blood transfusion, as a sexually transmitted disease, as a congenital infection, by needle sharing for intravenous drug abuse, or within a laboratory by intradermal inoculation of *L. donovani* promastigotes.[140,141] Very few cases of leishmaniasis have occurred as transfusion-transmitted infections in Europe or North America, with under 10 cases in infants or immunocompromised patients over the last 50 years. In endemic areas, this problem represents a much greater but unquantified risk.

Parasitology

Leishmania amastigotes live and multiply within macrophages by binary fission. They are round or ovoid bodies, approximately 2 to 3 μm in diameter. Occasional rupture of cells allows invasion of uninfected monocytes and macrophages by free forms. Sandflies ingest amastigotes within macrophages from blood or skin. In the insect's stomach, free amastigotes multiply and divide asexually, becoming elongated and developing flagella as metacyclic promastigotes. Within 2 weeks, such infective forms migrate through the lining of the stomach and enter the proboscis of the sandfly, allowing

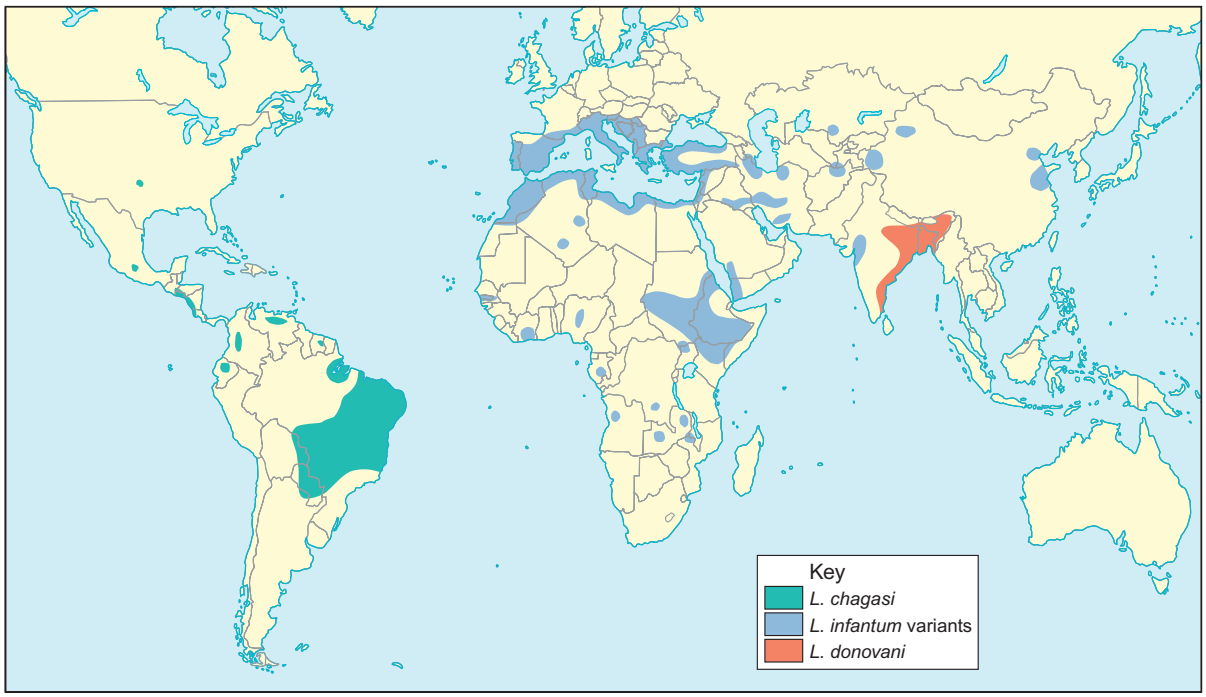

Figure 160-7 EPIDEMIOLOGY OF VISCERAL LEISHMANIASIS (VL). VL caused by parasites of the *Leishmania donovani–Leishmania infantum* complex occurs in the Mediterranean littorals, the Middle East, and adjacent parts of the former Soviet Union, the Sudan, East Africa, the Indian subcontinent and China, and South America *(Leishmania chagasi).* An arid, warm environment provides ideal ecologic conditions for the breeding of many species of sandfly. Zoonotic kala-azar due to *L. infantum* and *L. chagasi* is commonly associated with dry, rocky, hill country, where cases are typically scattered. In India, *L. donovani* is essentially an anthroponosis. This type of kala-azar may occur in severe epidemic fashion, as can kala-azar in the Sudan.

them to be inoculated in the human host while the sandfly takes a blood meal. Promastigotes are taken up by macrophages, where they become amastigotes by simple fission.

The large elongated fusiform promastigote measures 15 to 20 µm in length and 0.5 to 3.5 µm in width. Cultured promastigotes may also demonstrate rounded forms 4 to 5 µm in diameter. In Giemsa or other Romanovsky stains, a large nucleus and smaller distinct rod-like kinetoplast are obvious. The organisms must be distinguished from *Histoplasma capsulatum*.

Pathology

Parasites spread within macrophages to local lymph nodes and then to the liver, spleen, and bone marrow. They are also present more widely, in particular in the gastrointestinal tract and epidermis. In the subclinical cases, a cellular-mediated immune response causes a granulomatous lesion and resolution of the infection. However, in clinical VL little if any inflammatory response to the rapidly extensive and expanding parasite-laden macrophages is seen. Where it shows, a granuloma develops at the site of the initial inoculation but may not be apparent at the time of presentation.

Clinical Features of Visceral Leishmaniasis

The spectrum of clinical disease is wide, from asymptomatic infection to acute or chronic illness. Perhaps only 1% to 3% of all infections are symptomatic, with an incubation period of 10 days to 10 years, but it is typically between 3 and 6 months.

The high number of seropositive individuals in relation to clinical cases suggests that spontaneous cure without symptoms or with mild systemic symptoms and hepatosplenomegaly occurs in the majority of individuals. In a large series of children with VL in Brazil, the overall case fatality rate was 10%, and mucosal bleeding, jaundice, dyspnea, bacterial infections, and low neutrophil count of less than 500/mm^3 or low platelet count of less than 50,000/mm^3 were associated with a poor outcome.[142]

In endemic areas, a significant number of seropositive children, who do not develop classic VL, suffer a subclinical form of disease with malaise, fever, poor weight gain, intermittent cough, diarrhea, hepatomegaly, and variable splenomegaly. In these cases, leishmania were neither cultured nor seen in bone marrow aspirates.[143] There are also reports of VL presenting as mild nonspecific illness with fever, fatigue, cough, and abdominal pain in returning army personnel from the Middle East. In these cases, *Leishmania tropica* was isolated from bone marrow or lymph nodes.[144]

Patients with typical chronic VL often present with malaise and considerable fatigue and the slow onset of low-grade fever, anorexia, and weight loss. They usually have anemia, progressive and occasionally massive splenomegaly, hepatomegaly, lymphadenopathy, and hypergammaglobulinemia, with increasing skin pigmentation (hence the name *kala-azar* from the Hindi for "black sickness"). Patients may have jaundice, petechia, or purpura, heart murmurs, and edema. The size of the spleen is related to the length of infection and severity of the pancytopenia. In Africa, patients may have diffuse polymorphic papular lesions at presentation. Oral, nasal, nasopharyngeal, and laryngeal ulcers may occur during active disease or after treatment. The large spleen, often extending to the right iliac fossa, may be painful. Other features of acute disease include cough, epistaxis, and in some severe cases concurrent infection of the respiratory or gastrointestinal tracts and/or tuberculosis.

The typical features of VL may be preceded by bacteremia, bacterial infection, acute hepatitis, or Guillain-Barré syndrome. VL may be associated with hepatic necrosis, cholecystitis, or neuropathy. Occasionally lymphadenopathy may occur without systemic features of the disease. Here histology shows noncaseating granulomas and amastigotes within macrophages.

A more acute presentation in recent immigrants and visitors to endemic areas may include a high periodic fever, similar to classic malaria, with malnutrition, bleeding, hepatitis, and/or acute renal failure.

Immunocompromised Hosts

Coinfection of HIV and VL is now a well-recognized clinical entity in the Mediterranean and undoubtedly occurs more widely[145-147] (for review see references 148 and 149). VL occurs in the setting of late-stage acquired immunodeficiency syndrome (AIDS) with $CD4^+$ lymphocyte counts of less than 200×10^6/L. Patients present with fever, splenomegaly, and pancytopenia with frequent and sometimes atypical involvement of the gastrointestinal and respiratory systems and skin. The typical hematologic features of VL are sometimes absent, and serologic tests are often negative, although antibodies to 14- and 16-kDa *Leishmania* antigens may be detected by Western blot.[150] However, organisms are plentiful in bone marrow and even in buffy coat preparations. Some patients may have few symptoms, and the diagnosis of VL in immunocompromised patients requires a high index of suspicion. Treatment is difficult, with poor responses to pentavalent antimony. Liposomal amphotericin is the drug of choice. However, relapses are usual, and maintenance treatment is required.

VL may also occur after transplantation, after immunosuppressive treatments, including chemotherapy, rituximab, or other immunodeficiency states.[151,152] Although patients present with a typical combination of fever, pancytopenia, and splenomegaly, the diagnosis may be missed if not considered.

Hematologic Features

VL causes a moderate normocytic, normochromic anemia.[153] The pathogenesis of anemia is multifactorial and includes hemodilution, shortened red cell survival, and reduced erythropoiesis.[154] The plasma is low, with plentiful stored iron typical of the anemia of chronic disease.[155] One report has suggested that Epo levels are reduced compared to what would be expected for the degree of anemia.[156] Occasionally folate deficiency secondary to malabsorption and/or increased cell turnover or coexistent iron deficiency are associated with macrocytic or microcytic anemia, respectively.[157]

The direct Coombs test results are usually positive for C3 components, and IgG and anti-I agglutinins may be present, but the presence and strength of the test is not correlated with the severity of the anemia. The positive direct Coombs test results appear to be due to absorbed immune complexes onto erythrocytes.[158] The neutrophil survival is reduced, and the differential white blood cell count shows neutropenia, relative lymphocytosis, and low eosinophil levels, with a white blood cell count typically in the range 2 to 4×10^9 L.

Neutrophil function may be impaired.[159] Pancytopenia is more severe in those with concurrent HIV infection. A leukemoid reaction to infection has been reported.

Typically the platelet count is reduced to 50 to 200 10^9/L as platelet survival is reduced. Mucosal bleeding may occur, but extensive purpura is uncommon.

The prothrombin time is usually mildly prolonged to 2 to 4 seconds longer than control, secondary to impaired liver function. Fibrinolytic activity is increased, and in advanced cases fibrinogen levels may be reduced. Disseminated intravascular coagulation or vasculitis may occur.[153,159] Full coagulation screening is advisable if a splenic aspirate or bone marrow biopsy is planned.

The bone marrow is usually hypercellular, with increased erythroid, myeloid, and platelet precursors. Lymphocytes may be increased, and macrophages contain Leishman-Donovan bodies (Fig. 160-8).[160] If weight loss and malabsorption are extensive, the marrow may undergo gelatinous transformation.

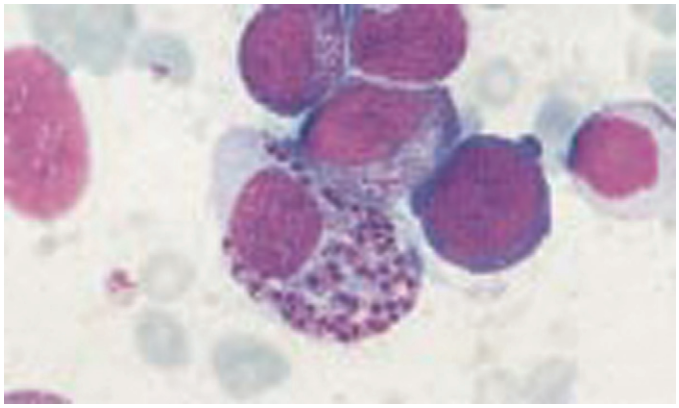

Figure 160-8 *LEISHMANIA INFANTUM* IN MACROPHAGE FROM BONE MARROW. Although typically found in macrophages as shown here, isolated extracellular amastigotes from disrupted host cells are commonly seen in such preparations.

The mechanism of leukopenia and thrombocytopenia is multifactorial. There is evidence for reduced bone marrow production of granulocytes and platelets and also for their autoimmune destruction and/or increased splenic clearance.

After treatment, hematologic recovery is slow and full recovery may take many months.[155]

Laboratory Features

The epidemiologic context and clinical features can suggest a diagnosis of leishmaniasis. Hematologic and biochemical tests are nonspecific; biochemical tests may show mild elevation of bilirubin and transaminase levels and more commonly raised level of alkaline phosphatase. Previously the nonspecific formol gel test was used to indicate hypergammaglobulinemia. Diagnosis is confirmed by direct examination of parasites by microscopy, culture, or polymerase chain reaction (PCR) (for a detailed review see references 161 to 163).

Morphology

The pathognomic amastigotes of *Leishmania* spp. can be found in a variety of sources. The diagnosis is often made by splenic puncture or by bone marrow aspiration where large numbers of amastigotes may be seen within macrophages. Amastigotes are stained using Giemsa or other Romanovsky stains and demonstrate a purple nucleus and the large anterior kinetoplast (see Fig. 160-8).

In nonimmunocompromised patients, splenic aspirates are positive in more than 95%, bone marrow aspirates positive in more than 85%, buffy coat macrophages positive in more than 70%, and lymph nodes positive in more than 60% of patients with VL. In practice, samples are taken from the least invasive sites first, although lymphadenopathy is not invariable.

Where coinfection of HIV and leishmania occurs, amastigotes are more reliably found in bone marrow than in peripheral blood and may also be demonstrated in biopsy specimens from a wide variety of sites. Biopsy material can be stained with polyclonal anti-*Leishmania* serum and indirect immunofluorescence. However, direct demonstration of parasites is less sensitive than culture or PCR.

Splenic Aspiration

Splenic aspiration is rarely performed in North America and Europe but is a common diagnostic procedure in endemic areas. Aspiration is contraindicated in the presence of a bleeding tendency, portal hypertension, or a splenic hydatid cyst. Splenic aspirates are obtained

from the middle of the long axis of the spleen. After cleaning the skin, a 21-gauge needle attached to a 5-mL syringe is inserted subcutaneously in line with the long axis of the spleen. The needle should be swiftly inserted to a depth of approximately 2 or 3 cm at an angle of roughly 45 degrees to the skin, applying negative pressure. The needle should be withdrawn immediately while maintaining negative pressure and only taking a few seconds for the entire procedure. The splenic tissue may be expelled from the needle using a small amount of air and by fixing the stain using standard procedures.

Culture

Amastigotes may be grown as motile promastigotes from aspirates on the classic Novy-MacNeal-Nicolle medium or other suitable media at 22° to 24° C, and populations double only every 2 to 3 days.[164,165] Inoculation of material into the susceptible golden hamster is no longer used to grow parasites.

Molecular Methods

The PCR may detect low levels of infection and has been used for diagnosis and monitoring of treatment and to determine the genotype of the parasites.[166,167] Blood from filter paper can be used to prepare DNA, but as for direct morphology, PCR from bone marrow samples is a more sensitive method to demonstrate parasites.[168] It may be particularly useful for monitoring treatment and relapse in HIV- and *Leishmania*-infected patients.[168] Isothermal DNA amplification methods are being applied to develop tests to be used where sophisticated equipment is not available.[169]

Serologic Tests

Serologic tests have to be interpreted in light of the clinical findings. The tests are useful to screen suspected cases or populations for VL. However, they are unreliable in immunocompromised patients, who frequently are seronegative in spite of patent infection. Conversely, those harboring a subclinical infection may be seropositive, but samples may fail to yield evidence of parasites. Finally, serologic findings are positive many years after treatment or self-cure.

An indirect IFAT or ELISA using freeze-dried *Leishmania* antigen has sensitivity and specificity greater than 95%. A DAT is also available with purified freeze-dried antigen and is a highly sensitive and specific test.[170] The freeze-dried antigen is very stable even when stored in extreme conditions.

The ELISA and immunochromatographic tests using *Leishmania* recombinant K39 antigen are 100% sensitive and more than 98% specific in Asia.[171,172] The sensitivity and specificity of the DAT and K39 immunochromatographic test are broadly similar, although the K39 test was less sensitive in the Sudan than in Asia.[173] An alternative target antigen for serologic tests such a recombinant K28 and rapid point-of-care test are now being developed.[21]

Treatment in patients without HIV coinfection may be monitored using urine antigen tests using detection of the K39 and K26 *Leishmania* antigens. These test results become negative 3 weeks after commencing treatment.

Management

General supportive care is important and includes correction of nutritional and hematinic deficiencies, blood transfusion in severe anemia, and antibiotics for secondary infections (for review of diagnosis, therapy, and management, see reference 162).

Specific chemotherapy for VL uses a number of potentially toxic drugs. Intercurrent infections must be identified and treated, and general measures include improvement of nutritional status (for review of treatment see references 174 and 175). Use of pentavalent antimonials, including sodium stibogluconate (Pentostam) and meglumine antimonate (Glucantime) are now limited, especially in South Asia, by increasing drug resistance. There is concern that drug resistance will develop to the alternative therapies, and combination treatment aiming at short courses that also delay the development of drug resistance are in progress.[53]

Amphotericin B is effective against *Leishmania* and is used in endemic areas where high levels of resistance to pentavalent antimonials are present. It may be given as a slow intravenous infusion in 5% dextrose over 4 to 6 hours, beginning at 250 micrograms/kg a day, increasing to 1 mg/kg until a total dose of 20 mg/kg has been given. Side effects include anaphylaxis, anemia, fever, bone chills, bone pain, and thrombophlebitis. Hypokalemia and hypomagnesemia are significant problems, and potassium loss and supplementation may be reduced by the concurrent use of amiloride to prevent renal tubular potassium leakage.[176]

Reduced toxicity from amphotericin is achieved using a liposomal amphotericin preparation (AmBisome), which has been made more widely available through preferential pricing in endemic areas. It is an effective and safe treatment and is used when affordable. A test dose of 1 mg should be given and then the recommended dose is 3 mg/kg/day on days 1 to 5, 14, and 21. Studies have shown a short course of treatment of the single infusion at 5 mg/kg or 5 daily infusions of 1 mg/kg have cure rates of over 90%. In patients with HIV, a dose of liposomal amphotericin at 4 mg/kg/day on days 1 to 5 followed by 4 mg/kg/day on days 10, 17, 24, 31, and 38 is recommended. The relapse rate is high, and close monitoring of patients is required.

Miltefosine is a new drug and effective orally against VL in India and Africa.[177,178] The current regime is 2.5 mg/kg/day for adults and children older than 2 years for 4 weeks. Higher than 95% cure rates have been achieved. Gastrointestinal upset occurs frequently. Miltefosine is teratogenic and may reduce fertility. It has a long half-life and has a low therapeutic index, which may contribute to the development of resistance, and so combination chemotherapy is being investigated to combat development of resistance.

Intramuscular paromomycin has been used at a dose of 20 mg/kg/day for 21 days. It has been shown to be equivalent to amphotericin B for the treatment of VL in India.[179] Moreover, patients treated for VL in Africa with sodium stibogluconate and paromomycin have an improved outcome compared with therapy with sodium stibogluconate alone.[180]

Post–kala-azar dermal leishmaniasis may occur in up to 10% of patients after treatment for VL. It is seen mainly in India and is common in Africa. It occurs after treatment of VL and may appear up to 10 years after treatment. It presents as a maculopapular rash spreading around the mouth, trunk, and limbs. These nodules and papules contain amastigotes. Prolonged treatment may be required to eliminate infection.

Leishmaniasis as a Transfusion-Transmitted Infection

Leishmaniasis poses problems as a potential transfusion-transmitted infection in endemic areas. The disease can be transmitted by blood and platelet concentrates, although leukodepletion by filtration reduces organisms by many orders of magnitude and so probably also the risk for transmission. In Europe, given the low absolute risk for transmission, donor deferral is used to reduce the risk for donation by anyone who is parasitemic.[181] However, surveys of blood donors in areas where the parasite is transmitted suggest parasite DNA can be detected in 0.3% to 1.75% of blood donors. It has been noted that service personnel returning from the Middle East represent a group of potential donors who may have been exposed to infection.[182]

AFRICAN TRYPANOSOMIASIS

African trypanosomiasis is caused by the flagellate protozoa *Trypanosoma brucei* ssp, named after David Bruce, a Scottish parasitologist

who first demonstrated the parasite in the blood of cattle affected by nagana. In man, Aldo Castellani demonstrated trypanosomes in the cerebrospinal fluid of patients with sleeping sickness. Bruce was able to show the protozoa in blood and showed that they were transmitted from antelopes to cattle by the tsetse fly and blood of patients suffering from sleeping sickness.

Epidemiology

Trypanosomes are transmitted by some species of the large and distinctive tsetse flies (*Glossina* spp.) in a sporadic distribution south of the Sahara and north of the Zambezi River. Of the three subspecies, *Trypanosoma brucei brucei* infects animals, whereas *Trypanosoma brucei gambiense* causes infection and sleeping sickness in Central and West Africa, and *Trypanosoma brucei rhodesiense* causes disease in East and Central Africa. *T. b. gambiense* is transmitted mainly between humans by the *Glossina palpalis* group in foci along watercourses in West and Central Africa. *T. b. rhodesiense* is transmitted by the *Glossina morsitans* groups widely distributed in the East African savannah. Here the disease is clearly a zoonosis, with antelopes and domestic cattle as reservoir hosts; it afflicts mainly hunters, guides, and game wardens and may occasionally occur in tourists on safari in the game parks of East Africa (Fig. 160-9).

Historically the disease has caused major epidemics, causing hundreds of thousands of deaths, and has prevented human settlement in large areas of Africa. Over 50 million people are now at risk for trypanosomiasis, and it has been estimated that the disease causes over 50,000 deaths each year. Most cases are reported in Zaire and northwestern Uganda, with a few hundred or fewer each year in neighboring East African countries.

Case finding and control measures have substantially reduced the risk for epidemics. Epidemics of disease have been associated with a breakdown in health services, for example, in villages in the areas of Lake Victoria in Uganda and more recently in Zaire, Angola, and southern Sudan (for review of current epidemiologic and clinical aspects of this disease see references 183 to 185).

Parasitology

The small, mobile trypomastigotes circulate and may be seen in peripheral blood. These flattened, fusiform organisms are pleomorphic, but are typically of a size similar to a red blood cell, approximately 20 μm long, and have an undulating membrane, attached to the protruding flagellum, extending from the anterior pole of the elongated body (Fig. 160-10).

Parasites multiply by binary fission and may cause chronic parasitemia and evade humoral immune responses by clonal antigenic variations of the major surface glycoprotein.[186]

When trypomastigotes are taken up in a blood meal by the tsetse fly, they multiply in the midgut by simple fission. Later they penetrate the wall of the gut and migrate to the salivary glands. There, as morphologically distinct epimastigotes, they become infective (or metacyclic) trypomastigotes 15 to 30 days after first infecting the fly. In endemic areas, up to 1% to 5% of flies may be infected. Flies remain infective until they die, several months later.

Pathology

The lymphatic, cardiac, and central nervous systems are involved by the disease. Initially proliferation of trypanosomes within lymph nodes and the spleen is accompanied by expansion of the lymphocytes, macrophages, and erythrophagocytosis. Polyclonal activation of lymphocytes results in high production of IgM and rheumatoid factor, and anti-DNA antibodies may appear. Later fibrosis and endarteritis supervenes with proliferation of endothelial cells and perivascular infiltration of plasma cells and lymphocytes. The liver shows infiltration of the portal tracts and fatty degeneration.

In *T. b. rhodesiense,* cardiac involvement may be extensive, with endocarditis, myocarditis, and pericarditis leading to extensive damage and death.

In the second stage of the disease, trypanosomes multiply within the central nervous system (CNS) and cause a chronic meningoencephalitis. Edema, hemorrhages, granulomatous lesions, and

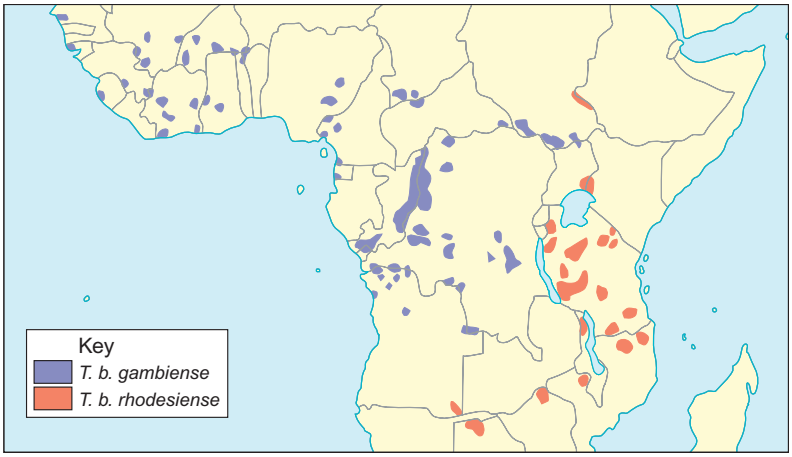

Figure 160-9 DISTRIBUTION OF *TRYPANOSOMA BRUCEI* INFECTION IN HUMANS. African trypanosomiasis is confined to equatorial Africa, with a patchy distribution depending on detailed topographic conditions. It is caused by two subspecies of *T. brucei*: *T. b. gambiense* infection is widespread in West and Central Africa, mainly by riverine species of tsetse fly *(Glossina),* but *T. b. rhodesiense,* transmitted mostly by savannah species, is restricted to the east and east-central areas, with some overlaps between the two. Although domestic pigs form an important reservoir for *T. b. gambiense* infection, various wild ruminants are the major sources for *T. b. rhodesiense*. The epidemic reemergence of African trypanosomiasis in recent years is exemplified by the death of at least 96 people in Angola in 2003, when 3115 cases were confirmed among a suspected 270,000 new cases in that country. In the same year it was estimated that some 500,000 people across Africa were suffering from trypanosomiasis, which was likely to have a mortality rate of approximately 80%. Recent reports indicate a spread of transmission from the northern toward the southern parts of Angola. *(Modified from WHO Map No. 98005.)*

Figure 160-10 ORIGINAL ILLUSTRATION OF *TRYPANOSOMA (TRYPANOZOON) BRUCEI GAMBIENSE* IN HUMAN BLOOD BY J. EVERETT DUTTON. Polymorphic trypanosomes were first discovered more than a century ago, in 1895, by David Bruce in the blood of domestic cattle suffering from the wasting disease nagana in South Africa. The first observation of these protozoa in humans was by R. M. Forde, who noted, in 1902, "small worm-like, extremely active bodies" in the blood of a sick European seaman in The Gambia. The parasites seen here in a Romanovsky-stained, thin blood film, which were described and named by Dutton in the same year, are responsible for sleeping sickness in West Africa. *(Reproduced by kind permission of the Director, Liverpool School of Tropical Medicine.)*

thrombosis contribute to cerebral degeneration. Lymphocytosis and plasma cells with large eosinophilic inclusions (Mott cells) may be found in the CNS.

Intriguingly, nonpathogenic species of African trypanosomes may be killed by the human high-density-lipoprotein particles astonishingly subverting a parasite pathway for heme uptake. The complex of haptoglobin-related protein and apolipoprotein L-1 (apoL1) are taken up into the parasite by a parasite glycoprotein receptor, which binds the haptoglobin-hemoglobin complex.[187-190] *T. b. rhodesiense* is resistant to killing by human sera because the apoL1, which induces parasite apoptosis, is neutralized in the lysosome by serum resistance–associated protein, which binds to a specific apoL1 domain. The selection of trypanolytic apoL1 variants have a cost. In African Americans, focal segmental glomerulosclerosis and hypertension-attributed end-stage kidney disease are associated with two independent sequence variants in the APOL1 gene.[191]

Clinical Features

T. brucei gambiense

Local inflammation at the site of inoculation causes a distinctive chancre or painful, indurated ulcer appearing 2 to 3 days after an infective bite and lasting for up to a month.

Trypanosomes multiply in the lymphatic system for 6 to 14 days before causing patent infection in the blood, characterized by waves of parasitemia and fever. Later, invasion of the CNS may occur by transit of organisms through the choroid plexus and/or endothelial cells.

In the blood stage of infection, fever, headache, and arthralgia are prominent. Lymphadenopathy is common, particularly in the posterior triangle of the neck (Winterbottom sign). There may be intermittent rashes (often circinate erythema), pruritus, or edema. Moderate splenomegaly occurs in 10% to 20% of patients. A few infected patients are asymptomatic.

This early stage of infection may last for up to 2 years or more before CNS involvement, although rapidly progressive disease may occur. The CNS phase of disease is marked by the progressive onset of headache, disinhibited behavioral changes, and mood, thought, and sleep disturbance. Wasting is prominent. Signs of diffuse CNS damage in the last phases of the disease include dementia, extrapyramidal and cerebellar dysfunction, and hyperesthesia. Tendon reflexes are increased and signs of upper motor neuron lesions widespread. Death usually occurs by intercurrent infection.

T. brucei rhodesiense

T. b. rhodesiense is more virulent, causing a more serious acute disease, with systemic features including serous effusions, hepatocellular jaundice, and a mild normocytic, normochromic anemia. Hepatosplenomegaly and lymphadenopathy are common, but involvement of cervical lymph nodes is less typical. Myocarditis is rare but may cause death before CNS involvement. Here CNS disease occurs sooner and is more rapidly progressive than *T. b. gambiense* infection and is fatal within 1 to 3 months.

Infection with *T. b. gambiense* may resolve in the vast majority of cases. Where infection persists, there is typically a long asymptomatic phase. Numerous lymph nodes are enlarged to 1 to 2 cm in diameter and are soft, mobile, and painless.

The differential diagnosis of trypanosomiasis includes malaria, typhoid, fever, and viral hepatitis in the acute phase, whereas lymphadenopathy may suggest infectious mononucleosis or tuberculosis. In the cerebral phase of the disease, syphilis, tuberculosis, HIV-associated cryptococcal meningitis, or chronic viral encephalitis must be considered.

Children

Those affected in utero may be born with CNS abnormalities. In children the disease is more rapidly progressive, and epileptic seizures and psychomotor retardation are the principal features of the disease.

HIV

The frequency of HIV seropositivity has been reported to show no significant differences between those presenting with trypanosomiasis and age-matched controls.[192,193] These results do not exclude that coinfections may modulate the course of the disease or the effectiveness of treatment.

Hematologic and Laboratory Features

The main hematologic features are a normocytic, normochromic anemia and moderate thrombocytopenia.[194] The anemia of trypanosomiasis is multifactorial. Hemodilution, hemolysis, and dyserythropoiesis or ineffective erythropoiesis all contribute to the pathogenesis. Hemolysis may be caused directly by lytic factors released by trypanosomes or indirectly by deposition of immune complexes and subsequent clearance of coated erythrocytes. In vitro studies have suggested that the variant surface glycoprotein from trypanosomes may be shed and taken up onto the erythrocyte membrane, where antibody and complement deposition could contribute to hemolysis. Bone marrow response is inadequate, and although the nature of the defect is unclear, there is failure in incorporation of iron into erythroid precursors as is seen in many forms of the anemia of chronic disease. In

mice infected with human trypanosomiasis, TNF-α contributes to bone marrow suppression, but detailed studies of the pathogenesis of anemia in human infections have not been reported. Serum IgM levels may be elevated to four times normal and with raised IgG levels cause an increased erythrocyte sedimentation rate.

The white blood cell count may be elevated with monocytosis, lymphocytosis, and circulating plasma cells, but eosinophilia is absent. Plasma cells with eosinophilic inclusion or Mott morular cells may occasionally be seen.

Petechia and purpura may be secondary to vascular injury, thrombocytopenia, and a complex but poorly defined coagulopathy. Abnormal liver function may cause prolonged clotting times. Functionally both thrombosis and fibrinolysis are increased, and fibrin degradation products (D dimers) are raised in acute disease, and in *T. b. rhodesiense* a frank disseminated intravascular coagulation may become evident.[195]

Examination of the bone marrow shows hypercellularity. Gelatinous degeneration may be seen in wasted patients.

Mononuclear cells are present late in the disease, and the cell count corresponds to the degree of neurologic involvement and may reach more than 300/μL in severely ill patients. The cerebral spinal fluid (CSF) protein levels are elevated (0.4 to 1.0 g/L).

As disease progresses, the circulating parasites become scarce. However, anemia and endocrine dysfunction, including amenorrhea, reduced libido, and impotence become apparent.

Parasitologic Assays

Direct detection of the parasite is particularly important in the light of the toxicity of the treatment.

Trypanosomes may be detected in lymph node aspirates and in wet and thick blood smears (Fig. 160-11). An aspirate may be taken from enlarged nodes. Aspirated fluid can be examined under a coverslip, and motile trypanosomes are typically seen at the edges of the coverslip.

Trypanosomes can be seen in wet smears, where a drop of blood is placed on a slide and examined under a coverslip. Alternatively, thick or thin Giemsa-stained blood films are made as for malaria diagnosis. The sensitivity may be increased by microcentrifugation.[196]

More recent methods to detect the low levels of parasitemia seen in *T. b. gambiense* include quantitative examination of the buffy coat using acridine orange[197] and small-scale ion-anion exchange chromatography.[198] Erythrocytes are retained in the column, whereas trypanosomes are eluted and are visible after concentration by centrifugation. The sensitivity of detection with these methods ranges from 10^4 per mL for wet smears to 10^2 per mL for ion-exchange columns and centrifugation. In *T. b. rhodesiense,* examination of the blood is more likely to yield a positive result than aspiration of lymph nodes.

Inoculation of the aspirate or samples into susceptible animals or in vitro culture has been used to detect low-level parasitemia. Mice and rats were used to detect *T. b. rhodesiense*, whereas the multimammate rat *(Mastomys natalensis)* and guinea pigs were used for *T. b. gambiense.* PCR of the 18S ribosomal RNA gene can detect parasites with similar sensitivity to parasitologic and serologic methods.[199]

Cerebrospinal Fluid

Trypanosomes may be found in the CSF as disease progresses, although a double centrifugation technique may be required to demonstrate organisms. In this technique 5 to 10 mL of CSF is centrifuged and the sediment taken up into a capillary tube and recentrifuged before examining the capillary tube under a coverslip (Fig. 160-12).[200] Specific molecular markers for this stage of CNS disease are being sought by proteomic analysis of the CSF.

Serology

Serologic tests are used for passive population screening in control programs (for review see reference 201). A Card Agglutination Test for Trypanosomiasis (CATT) is robust and can be used without extensive laboratory facilities.[202,203] The test contains freeze-dried trypanosomes with the LiTat 1.3 variant antigens and can be obtained from the Institute of Tropical Medicine, Antwerp (www.itg.be/itg/). It is quite sensitive (>95%) but lacks specificity due to cross-reactivities with animal *Trypanosoma* spp. Although useful as a patient screening

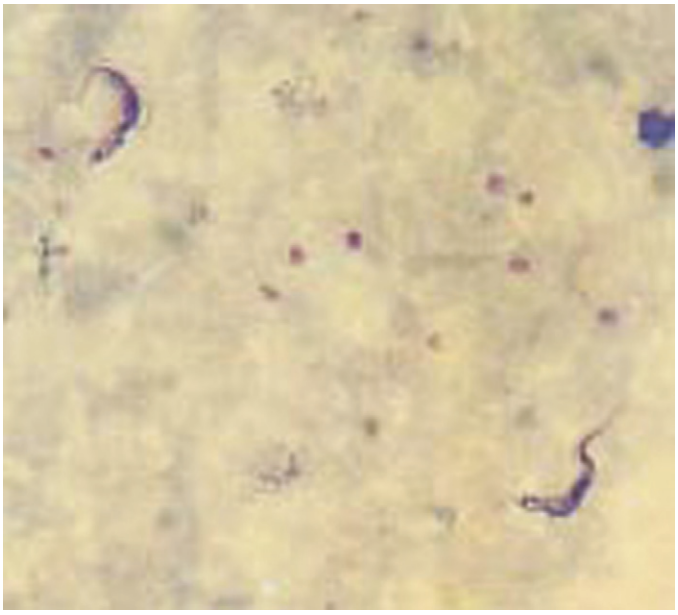

Figure 160-11 *TRYPANOSOMA BRUCEI RHODESIENSE* IN HUMAN BLOOD. *T. brucei brucei* parasitizes wild and domestic animals but does not infect humans. The different subspecies can be distinguished with certainty only by biochemical techniques, such as electrophoretic typing of their isoenzymes or by the use of deoxyribonucleic acid (DNA) probes. *T. brucei gambiense* and *T. b. rhodesiense* (and *T. b. brucei* of animals) are virtually indistinguishable in blood films. Note the small kinetoplast and free flagellum. Both subspecies from humans will infect guinea pigs, but only *T. b. rhodesiense* is infective to rats, in which the parasites are polymorphic, that is, long, thin, intermediate and short, stumpy forms of trypomastigotes may coincide.

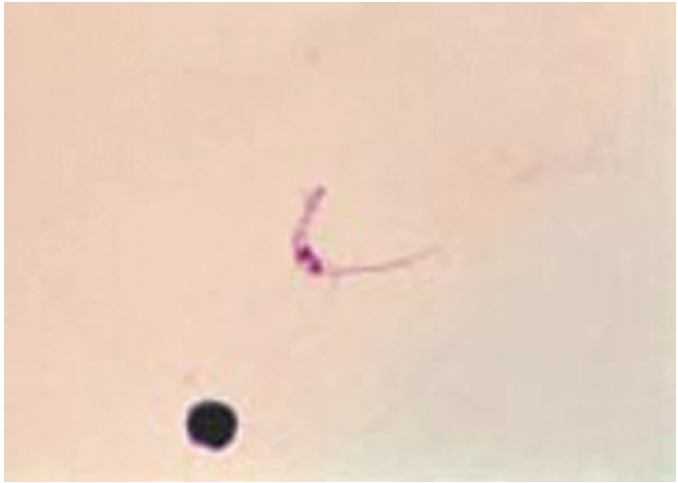

Figure 160-12 TRYPOMASTIGOTE OF *TRYPANOSOMA BRUCEI BRUCEI* IN CEREBROSPINAL FLUID. A single organism is seen in this sample taken from cerebrospinal fluid filtered in a "minicolumn."

test in a hospital for suspected cases of trypanosomiasis, the predictive value for positive test results falls when screening populations for active cases. It has nevertheless been reported to double the number of active cases found. Some patients may have false-negative results using this test if they are infected by parasites that do not express this variant antigen. Further versions of this assay have been developed to use dried blood on filter paper, namely the micro-CATT and macro-CATT, but these are less sensitive than the whole blood assay.

In *T. b. gambiense* serologic tests are not widely available, and direct examination of blood and CSF for parasites is the first line of investigation.

The card indirect agglutination trypanosomiasis test (TrypTect CIATT) can detect circulating antigens in *T. b. gambiense* and *T. b. rhodesiense* infection by latex agglutination. The sensitivity of the test is 95.8% for *T. b. gambiense* and 97.7% for *T. b. rhodesiense* and so significantly higher than that of lymph node puncture, microhematocrit centrifugation, and CSF examination after single and double centrifugation.[204]

A rapid latex agglutination test (LATEX/*T. b. gambiense*) contains a mixture of three variable surface antigens of the bloodstream form of trypanosomes and has been used to detect antibodies in patients infected with *T. b. gambiense*. At 1 : 16 serum dilution, test specificity was 99%, whereas sensitivity ranged from 83.8% to 100% depending on the geographic origin of the samples. The test sensitivity falls to 66% for CSF samples from second-stage patients.[205] A rapid latex agglutination test, LATEX/IgM, for the semiquantitative detection of IgM in CSF is available.[206] Finally, immunofluorescence assays and ELISA tests for antibodies using whole parasites are highly sensitive and specific, although less practical for mass screening.[207]

Treatment

Treatment of trypanosomiasis depends on the subspecies of trypanosome present. The drugs may be difficult to source and are toxic, so treatment requires expert help.

Early-stage *T. b. gambiense* may be treated with pentamidine for 14 days (intravenously [IV] or more usually intramuscularly [IM], 4 mg/kg/day). Hematologic side effects include neutropenia, and more general side effects include hypotension, hypercalcemia, hyperkalemia, renal failure, and hyperglycemia. Pentamidine will not cure CNS disease, and so examination of the CSF is required after initial treatment of the blood-stage disease.

Eflornithine (α-difluoromethylornithine) for 14 days (IV; 100 mg/kg, 6 hourly) is effective for CNS treatment for *T. b. gambiense*.[208] It is a toxic drug suppressing DNA replication by inhibition of ornithine decarboxylase and thus polyamine synthesis and DNA replication. It causes dose-dependent bone marrow suppression with anemia, neutropenia, and thrombocytopenia in the majority of patients. The effects are reversible and are rarely dose limiting. It is effective neither in children nor in coinfection with HIV, where melarsoprol is required.

Melarsoprol is a trivalent organic arsenical compound and is more toxic but cheaper than eflornithine. It is used in Africa for the treatment of late-stage CNS trypanosomiasis. It is given as three daily IV injections, at a dose of 3.6 mg/kg up to 180 mg, on two occasions a week apart. If the CNS leukocyte count is greater than 20/mm^3, a further three injections are given a week later.

Melarsoprol causes a secondary encephalopathy in 5% to 10% of treated cases and is fatal in half of these.[209] The incidence and severity of encephalopathy may be reduced by concurrent administration of prednisolone (1 mg/kg/day up to 40 mg) started 1 to 2 days before melarsoprol treatment.[210] When steroids are used, it is necessary to give patients antimalarial and antihelminthic therapy, especially if *Strongyloides stercoralis* is present.

Prior treatment of blood-stage disease with pentamidine may reduce antigen levels and possibly adverse events. Promethazine, anticonvulsants, and antiemetics are important adjunctive treatments before commencing CNS therapy.

Polyneuropathy occurs in 10% of cases treated with melarsoprol and may be severe, causing quadriplegia. If neuropathy is suspected, melarsoprol should be stopped immediately and thiamine (100 mg, three times a day) given until symptoms subside.

Patients require prolonged specialist follow-up over 2 years, including blood and CSF examination for parasites. A rising CSF leukocyte count is a good guide to CSF relapse even in the absence of a demonstration of parasites.[211]

In treatment for early-stage *T. b. rhodesiense,* suramin is given as five IV injections (20 mg/kg, up to 1.5 g) on days 1, 3, 6, 14, and 21. Adverse effects include fever, proteinuria, paresthesia, pruritus, and urticaria. Hemolytic anemia, agranulocytosis, and thrombocytopenia have been reported as side effects.

Combination therapies of the antitrypanosomal drugs nifurtimox and eflornithine and also the combination of melarsoprol and nifurtimox are under trial for the treatment of second-stage disease to increase the efficacy of treatment and to overcome increasing drug resistance.[212]

Trypanosomiasis as a Transfusion-Transmitted Infection

Trypanosomiasis is a transfusion-transmitted infection. Asymptomatic or early-stage patients with trypanosomiasis are clearly a threat to the blood supply. Patients are excluded in the United Kingdom, Europe, and North America by the general donor queries relating to fever and constitutional symptoms.

In endemic areas, exclusion of infected donors with early-stage *T. b. gambiense* is clearly a more complex problem because patients may be asymptomatic for long periods of time if the degree of risk is unknown and no specific screening procedures are in place.

In summary, hematologic involvement in trypanosomiasis is peripheral to the main two features of the disease, but examination of lymph node aspirates, blood, and CSF is essential for diagnosis and management of the disease. Occasional patients may become severely ill and have complex hematologic abnormalities. In endemic areas, trypanosomiasis may pose a risk to the blood supply.

AMERICAN TRYPANOSOMIASIS

American trypanosomiasis (or Chagas disease, named after the Brazilian parasitologist Carlos Chagas) is caused by infection with *Trypanosoma cruzi*. This flagellated protozoon is transmitted by the triatomine insects, the reduviid bugs. The acute phase of infection is characterized by fever and high parasitemia, followed by a chronic phase with positive serologic results and low parasitemia but with end-organ damage to the heart, peripheral nervous system, and gastrointestinal tract, causing a chronic cardiomyopathy, neuropathy, and megaesophagus and megacolon.

Epidemiology

Chagas disease may occur in the Americas from the southern United States to Chile, but the highest prevalence is in Bolivia and Brazil (Fig. 160-13). There are approximately 10 million seropositive people in Latin America, and the number of people infected and the incidence of new infection is falling rapidly.[213] Infections are found not only in rural areas but also in recent immigrants to urban areas in North and South America and to Europe.[214] It is estimated that approximately 100,000 seropositive individuals are living in the United States. True, endogenous (autochthonous) infection in the United States is vanishingly rare, but seven such human infections have been reported in Texas, California, Tennessee, and Louisiana. Visitors to endemic areas are only rarely infected, with only a handful of cases being recorded in intrepid travelers spending time in traditional housing in rural areas. The range of reservoir hosts and species of triatomine bugs transmitting infection is wide.

Figure 160-13 DISTRIBUTION OF CHAGAS DISEASE. Human infection is endemic in parts of Central and South America from the Andes to the Atlantic coast and as far south as the latitude of the River Plate (Río de la Plata) shown here in green. Two major intergovernmental programs were started in 1991 to eliminate domestic vectors by a combination of spraying residual insecticides in houses, the use of insecticidal paints, and the deployment of fumigant canisters. The countries covered in the two initiatives, the second of which started in 1997, are shown in the figure. The latter program instituted universal blood screening to avoid transmission from infected blood donors. In less than a decade, remarkable progress has been made. Transmission (by the major vector, *Triatoma infestans*) was eliminated in Uruguay by 1997 and in Chile by 1999. Major reductions in transmission have also been reported from other endemic countries but, to date, not complete control. *(Southern Cone Initiative; Andean and American Initiative areas.)*

Parasites may also be transmitted by blood transfusion (see later), vertically from mother to child by breastfeeding, organ transplantation, and rarely by sexual transmission. Several outbreaks in Brazil have been reported after contamination of food by triatomine bugs and their feces. Laboratory infection by accidental ingestion or inoculation of parasites is well recorded.

Parasitology

T cruzi parasites are from the order Kinetoplastida and family Trypanosomatidae, existing as infective trypomastigotes in the bloodstream of vertebrate hosts. These organisms are fusiform cells, 10 to 20 μm in length, with a distinctive large posterior kinetoplast, containing mitochondrial DNA. They can enter phagocytes, muscle and nerve cells, and a wide variety of other cell types and here transform to oval amastigotes 2 to 5 μm in diameter. They multiply by fission, and amastigotes develop into mature trypomastigotes released on rupture of the cell to begin a new cycle of invasion and multiplication.

Slender, highly motile and broader, less motile trypomastigotes have been distinguished, which may be relatively more infective for host cells and insects, respectively.

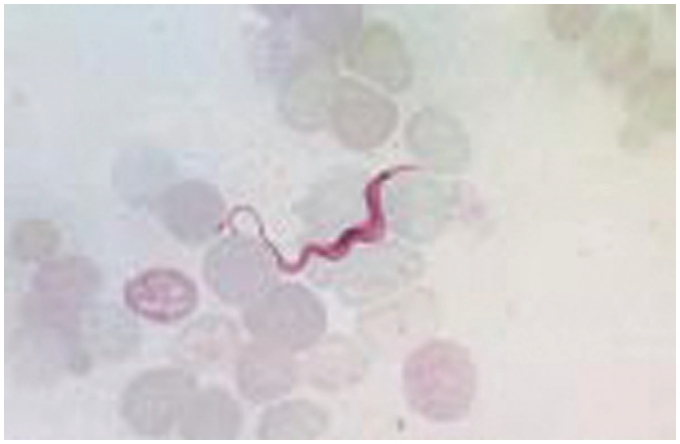

Figure 160-14 *TRYPANOSOMA RANGELI. T. rangeli* is a long, slender trypanosome also transmitted by reduviid bugs from wild animals to humans. It is readily distinguished by its shape from *Trypanosoma cruzi* in blood films and appears to be nonpathogenic to humans.

The species of triatomine bugs that commonly transmits disease is able to cause extensive infestation of simple mud-and-wattle thatched houses in rural Latin America,[215] where Chagas disease is a disease of poverty associated with poor housing. These bugs are infected by circulating trypomastigotes after taking a blood meal on sleeping victims. In the mid gut, trypomastigotes transform into epimastigotes and multiply by fission, before migrating to the hind gut where they develop into metacyclic trypomastigotes, adherent to the epithelium of the rectum. These infective forms are excreted into the feces and people are infected by rubbing this infected material from the bug into the skin or conjunctival membranes. In the human host, multiplication into macrophages is followed by rapid dissemination of trypomastigotes into the blood and hence to tissues.

The genome sequence of *T. cruzi* has stimulated a plethora of comparative and genomic approaches to the study of the parasite.[216,217]

Trypanosoma rangeli Infections

The nonpathogenic trypanosomes can be transmitted directly to people by the bite of the triatomine bugs, and they exist only as circulating trypomastigotes. No tissue amastigotes exist. Circulating organisms are sparse, but sometimes diagnosis can be made by careful microscopic examination of the distinctive morphology of these organisms in blood smears. The anterior position of the nucleus and small kinetoplast distinguish it from *T. cruzi* (Fig. 160-14). The antibodies produced to *T. rangeli* cross-react with those from *T cruzi* and hence cause false-positive serologic test results for *T. cruzi*. However, the species may be differentiated by xenodiagnosis or molecular genetics in specialized laboratories.[218] The importance of recognizing this nonpathogenic infection is to avoid unnecessary treatment for *T. cruzi*.

Pathology

There is a wide variation in the pathogenicity of isolates and some regional variation in the clinical spectrum of acute and chronic illness. Molecular typing has demonstrated considerable heterogeneity of *T. cruzi* isolates, although the association between strains of parasite and the outcome of infection are unclear. Clearly the organism must have many mechanisms of the immune evasion to cause chronic infections in a high proportion of individuals. Some of these have been elegantly defined, including resistance to activation of the alternate pathway of complement, specific mechanisms of entering the host cells, and evasion of intracellular killing by the oxidative burst and lysozymes.

Both $CD4^+$ and $CD8^+$ T cells are important for killing *T. cruzi*–infected cells, and interferon-γ has shown to be important to controlling disease, whereas transforming growth factor-β (TGF-β) and IL-10 enhance parasite replication (for review see reference 219).

End-organ damage occurs after tissues have been infected by *T. cruzi* amastigotes, but the mechanisms leading to extensive cell damage are not clear. After multiplication, tissue amastigotes form pseudocysts in the heart with little or no inflammatory reaction, although occasionally acute myocarditis with focal hemorrhage and inflammation may lead to heart failure. As the disease progresses, the inflammatory response is increased and is associated with increased tissue damage. There may be an autoimmune component to this inflammatory response, but the precise pathogenesis is poorly understood.[220] In the heart, chronic myocarditis leads to a decline in cardiac function. In late-stage disease, amastigotes can be found in almost all organs. Acute myocarditis with focal hemorrhage and inflammation may also lead to heart failure. Involvement of the brain, meninges, liver, lymph nodes, and spleen is common. Damage to the muscle walls and intramural nerve plexus in the esophagus and colon leads to dilation of these structures in the later phases of the disease.

Clinical Features

In about half the patients, a granuloma (or chagoma) occurs where parasites have been inoculated. The tender erythematous papule becomes keratotic and later heals, forming a hyperpigmented scar. When the conjunctiva are inoculated, the extensive unilateral periorbital edema may be prolonged (Romaña sign).

The severity of the acute illness is variable and ranges from asymptomatic infection or a mild febrile illness to a severe, potentially fatal illness with cardiac failure and meningoencephalitis in a minority of cases. Myalgia, generalized lymphadenopathy, hepatosplenomegaly, headaches, facial or generalized edema, vomiting, diarrhea, and anorexia are common features of the acute disease. The disease may be worse in children. The acute illness typically resolves in 4 to 8 weeks.

Chagas disease must be distinguished from typhoid fever, VL, brucellosis, toxoplasmosis, and malaria in cases of chronic, febrile illness in endemic areas.

Chronic Disease

The acute phase of *T. cruzi* infection is followed by a variable latent or indeterminate phase with no clinical symptoms. Indeed, patients may never present with signs of end-organ damage. However, up to a third of clinically infected patients may develop cardiac involvement and show right bundle branch block, AV conduction abnormalities, and/or abnormal T and Q waves. The patient may experience palpitations, chest pain, edema, and dizziness or syncope or dyspnea. The heart is enlarged, and intramural thrombus may cause sudden death.

In a further minority of chronically infected patients, the gastrointestinal tract is infected with abnormal motility of the esophagus and colon, leading to dysphagia and/or severe constipation. Occasionally other hollow organ systems may be affected.

Pregnancy and Congenital Infection

In pregnant women, Chagas disease can cause spontaneous abortion, premature birth, intrauterine growth retardation, and stillbirth. Congenital infection occurs in 1% to 2% of women with chronic infection. Prompt diagnosis of circulating parasites in neonates at risk for congenital Chagas disease is essential to beginning early treatment. It is recognized that infection can also be transmitted by breastfeeding. Most children are asymptomatic, but 10% to 20% of children have a mild systemic illness with hepatosplenomegaly. More severely affected newborn children have pneumonitis, meningoencephalitis, and diffuse dermal granulomas. Petechiae, purpura, and a generalized bleeding tendency may occur.[221]

Immunocompromised Patients

The disease may recrudesce after chemotherapy for malignant disease, immunosuppressive therapy, or after organ transplantation. The clinical disease may be fulminating with obvious parasitemia. Irregular erythematous indurated lesions have been described during *T. cruzi* recrudescence after solid organ transplantation. Here tissue amastigotes can be demonstrated by fine-needle aspiration.

HIV

Coinfection with *T. cruzi* and HIV has been reported from urban centers in Brazil. *T. cruzi* develops in end-stage disease with $CD4^+$ T-cell counts of less than 400/μL. Patients may be severely ill, the majority with meningoencephalitis and often with a space-occupying lesion. Typically the CSF shows a mild lymphocytosis (<100 cells/μL). Parasites may be seen in the blood and occasionally the CSF. Cardiac involvement and heart failure is common.

Hematologic and Laboratory Features

A mild normocytic, normochromic anemia is typical of acute illness. The pathogenesis of the anemia and contributions of hemolysis and bone marrow depression have not been studied in humans, but in experimental infections in mice, uncontrolled infection and TNF-α can be shown to contribute to depressed hematopoiesis. A modest lymphocytosis and increases in liver and muscle enzymes may be present. Nonspecific electrocardiographic changes, first-degree heart block, and cardiomegaly suggest early myocardial involvement.

Hematologic abnormalities are not usually found in the late stage of disease, in which cardiomyopathy with cardiac failure, rhythm disturbance, and angina and systemic emboli from intramural thrombus may occur. Trials of systemic anticoagulation have not been conducted.

Diagnosis

Microscopy

During the acute phase of the disease, motile trypanosomes can be identified in wet preparations or buffy coat preparations using concentration methods and detailed morphologic examination, including Giemsa-stained gently prepared thick and thin films to avoid damage to parasites (Fig. 160-15). Trypanosomes can be aspirated from the chagoma in the acute phase of disease and visualized in a wet preparation of needle aspirates. Parasites may occasionally be found in lachrymal fluid.

Sensitivity is increased by the concentration methods described for *T. brucei* earlier. Organisms may also be sought in centrifuged serum after blood has clotted or by centrifugation after lysis of red blood cells with 0.8% ammonium chloride. Trypomastigotes can also be detected in other specimens, including CSF, bone marrow, pericardiac fluid, and tissue biopsy specimens. Organisms must be distinguished from the morphologically similar nonpathogenic *T. rangeli* (see Fig. 160-14 and earlier).

After the acute phase, circulating parasites are not visible, although inoculation of blood into susceptible animals (xenodiagnosis), in vitro culture, or molecular methods may demonstrate patent infection. Parasitemia may be obvious in immunocompromised patients in the chronic phase of disease.

Xenodiagnosis

Infection of laboratory triatomine bugs by a seropositive patient is more sensitive than morphologic examination in chronically infected

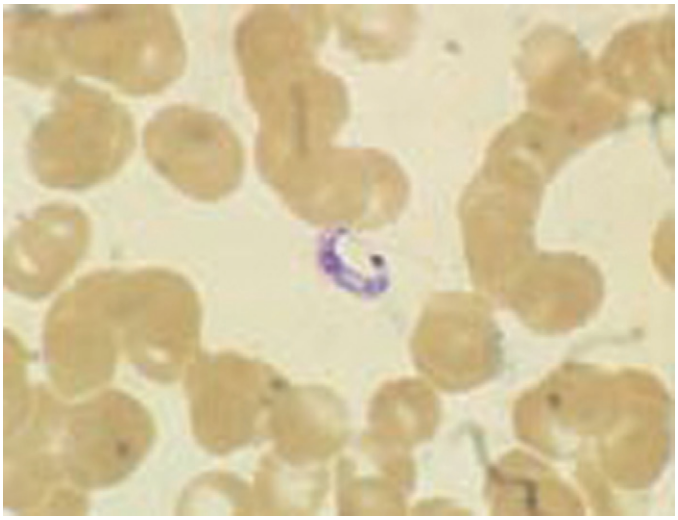

Figure 160-15 *TRYPANOSOMA CRUZI* IN HUMAN BLOOD FILM. The causative agent occurs in blood films characteristically as short C-shaped or S-shaped trypomastigotes with a prominent kinetoplast. It is otherwise monomorphic.

patients. It is also possible to infect susceptible laboratory animals. However, these techniques are only available in specialized centers in Latin America.

In Vitro Culture

Epimastigotes can be cultured using blood agar (Novy Nichol MacNeal [NNN]) medium or other media such as Schneider insect medium. After 4 weeks or more culture at 26° C, epimastigotes may be detected.[222,223]

Serology

Serologic testing is a sensitive method of detecting infection after the acute phase. In Latin America, a number of commercial assays are available using crude epimastigote lysates in a variety of different formats. Serologic tests have used IFAT and ELISA using crude antigen prepared from in vitro cultures of epimastigotes. These tests must be carefully controlled with appropriate positive or negative sera. Chronically infected patients usually give a positive test result if titers are greater than 1:80.[224] These have a sensitivity and specificity of more than 95%. These antibodies may cross-react with antibodies to malaria, leishmaniasis, syphilis, and some autoimmune conditions. ELISA should be used in conjunction with a confirmatory test such as a Western blot.

In South and North America, a number of companies market ELISA-based assays using recombinant antigens, synthetic peptides, or a concentrated extract of excretory-secretory antigens from either Brazil or Tulahuen strain *T. cruzi* trypomastigotes (total trypomastigote excretory-secretory antigens [TESAs]). These assays may provide more rapidly available and cheaper tests without loss of sensitivity and specificity (see Trypanosomiasis as a Transfusion-Transmitted Infection for further discussion).

Serologic testing may be useful in the evaluation of people who may have been exposed to Chagas disease, pregnant women, and patients about to undergo immunosuppressive treatment or to receive chemotherapy or who have been diagnosed with HIV or other immunosuppressive illness. Children born to seropositive women will have maternally derived IgG anti–*T. cruzi* antibodies but demonstrate IgM anti–*T. cruzi* antibodies if congenitally infected.[225]

Molecular Diagnosis

Amplification of *T. cruzi*–specific sequences by PCR is potentially the most widely applicable, sensitive, and specific method for detecting parasites. A number of assays have been developed, based on the application of repetitive sequences in kinetoplast DNA. A metaanalysis has suggested that PCR is not more sensitive than ELISA for detection of *T. cruzi* in chagasic patients.[226]

Treatment

The detailed treatment of Chagas disease is beyond the scope of this chapter. Treatment of the acute, intermediate, and chronic phases requires expert supervision because parasitologic cure is achieved in only half the cases and monitoring progress requires specialist testing and evaluation and where necessary treatment of end-organ damage. The current and potential future chemotherapy[227-229] have recently been reviewed.

Nifurtimox is a synthetic nitrofuran that inhibits pyruvic acid synthesis by inhibition of lactic dehydrogenase. It is given for 30 to 120 days at 3 to 5 mg/kg three times a day. The most serious side effects are peripheral neuropathy, mental disturbance (including psychosis), and hemolytic anemia associated with G6PD.

Benznidazole is widely available in Latin America and is given at 2.5 to 5 mg/kg twice a day for 30 to 60 days. Severe hematologic complications are common, and bone marrow depression is a serious side effect. Thrombocytopenia may be severe, and neutropenia may progress to agranulocytosis. Other serious complications include photosensitivity, neuropathy, and weight loss.[230]

Supportive therapy is required for heart failure and acute meningoencephalitis. Surgery may be required for alleviation of esophageal and chronic dysfunction. In the absence of effective or simple therapy, control of triatomine bugs and an improvement in the housing stock are essential to prevent and control disease.

Trypanosomiasis as a Transfusion-Transmitted Infection

Chagas disease may occur as a transfusion-transmitted infection and represents a real threat to the safety of the blood supply in endemic areas. It is estimated that 1.5% to 50% of contaminated units cause infection in recipients, a wide range that may reflect the stage of infection in the donor, the type and processing of the component, and the immune status of the recipient.[231]

In endemic areas, seropositivity is high, reaching 50% in some areas of Bolivia and 1% to 2% in major areas in Brazil. Control of blood transfusion–transmitted infection is part of the World Health Organization strategy for control of Chagas disease.[232-234] Serologic screening, tests using synthetic peptide antigens, or a mixture of recombinant antigens to detect anti–*T cruzi* antibodies in chronically infected blood donors, are more than 95% sensitive.[235,236] These serologic tests, replacing those based on crude antigens, have allowed improved coverage of screening of blood donors throughout Latin America.[237,238]

It is possible to treat blood with gentian violet (0.25 g/L for 24 hours at 4° C) or with methylene blue to kill circulating organisms. It has also been shown that amotosalen or riboflavin plus ultraviolet A photochemical inactivation technology is effective in inactivating *T. cruzi* in platelet concentrates and plasma.[238,239] In addition, prophylactic benznidazole can be given to immunosuppressed patients receiving blood products in endemic areas.

Outside Latin America, Chagas disease is an occasional cause of transfusion-transmitted infection, mainly in immunosuppressed patients. It is possible that minor infections are not recognized in healthy individuals. Clearly the high rates of seropositivity in individuals from endemic areas suggest that recent immigrants may easily transmit the disease.

In the United Sates, the overall seropositive rate among blood donors is 1:250,000, with local incidence rates reaching 1:7500 or

greater in Los Angeles and Miami.[231] These rates are probably underestimates because immigration from endemic areas has recently increased. Surveys of blood donors in France have shown seropositivity of *T. cruzi* can be detected by PCR in about half the seropositive donors and remain viable for at least 20 days, surviving cryopreservation and thawing. *T. cruzi* has been reported to be transmitted after organ transplantation[240,241] and after blood transfusion in seven patients who were immunosuppressed.[242-246]

Donors can be excluded by a medical questionnaire eliciting obvious symptoms of acute or chronic disease. Prospective studies have shown these questionnaires would miss many infected donors,[247,248] including those infected congenitally.[249] Nevertheless, in Europe screening for anti–*T. cruzi* antibodies is targeted at at-risk blood donors who originated from an endemic area, donors with mothers originating from such an area, and individuals who have lived in or traveled to endemic areas. In France the seropositivity in these selected donors was 1:32,000.[250]

In the United States, new tests have been requested by the Food and Drug Administration to combat this threat. A radioimmunoprecipitation assay (RIPA) is the most sensitive method to detect anti–*T cruzi* antibodies,[251] although RIPA cross-reactivity has been reported in patients with VL.[252] It is, however, unsuitable for mass screening. An ELISA based in a concentrated extract of excretory-secretory antigens from either Brazil or Tulahuen strain *T. cruzi* trypomastigotes (TESAs)[253,254] had an overall sensitivity of 100% and specificity of more than 94%, and a prototype *T. cruzi* lysate–based ELISA has been developed and appears to be 97.7% sensitive and 100% specific.[251]

It is only to be hoped that sensitive screening tests are consistently applied to reduce transmission of Chagas disease by blood products in endemic and nonendemic countries. On a more general note, it is encouraging that the initiatives to control *T. cruzi* infection across Latin America are showing real evidence of success.[213,255]

BABESIOSIS

Babesiosis is an intraerythrocytic infection caused by parasites from the order Piroplasmida and the family Babesiidae. It was first observed as causing parasitic inclusions in erythrocytes of cattle in Romania by Victor Babes at the end of the 19th century.[256] The infection is zoonosis transmitted by hard-bodied ticks and causes fever and hemolytic anemia.[257] Several distinct *Babesia* spp. cause disease in different geographic areas.[257,258]

There are two well-defined *Babesia* species that cause human infection. *Babesia microti* is a parasite of small rodents in the northeastern United States and is spread by nymphs, larvae, and adult forms of the hard-bodied ixodid ticks *(Ixodes dammini)*. Infection of the white-tailed deer by ticks allows multiplication and spread of the infected ticks. Infections can be transferred to humans by all forms of the tick after prolonged feeding. The infection is therefore most common in people holidaying or working in forested areas of the northeastern United States. The offshore islands of Nantucket, Martha's Vineyard, Block Island, and Shelter Island are foci of disease, but it also occurs in northeastern and upper midwestern states, particularly Connecticut, Rhode Island, Delaware, and New York State. Hundreds of cases have been recorded since the first identified case in 1969. Visitors and workers in endemic areas should avoid tick bites using appropriate clothing and repellents.

In Europe, *Babesia divergens* and the morphologically indistinguishable parasite *Babesia bovis* are transmitted to humans by ticks *(Ixodes ricinus)* from cattle. Less than 50 cases have been recorded. European cases of *B. microti* and *Babesia canis* infection have also been reported.[257]

A handful of cases of infections with poorly defined *Babesia* spp. have been reported from the western United States. These organisms are morphologically indistinguishable from *B. microti* but are distinguished by molecular methods. The MO1-type piroplasm has caused illness in an index case in Missouri in 1992, and the WA1-type and CA1-4 piroplasms caused disease in five cases reported from Washington State and California, respectively, in 1994.[259,260] A further *B. microti*–like organism has been isolated from an asymptomatic woman in Taiwan.[261]

B. microti and the WA1-type piroplasms have been transmitted by blood and platelet transfusions. Transplacental infection by *B. microti* has been reported.

Parasitology

Parasites appear to be introduced into the bloodstream, where they invade erythrocytes. There they multiply by asexual fission to produce two to four merozoites. These infective forms are released after lysis of the erythrocyte and begin another cycle of invasion multiplication. Parasites are cleared by macrophages. The contribution of antibodies and cell-mediated immune response has not been defined, although *B. bovis* expresses clonally variant antigens on the surface of infected erythrocytes.[27]

Clinical Features

The North American *B. microti* infections have an incubation period of several weeks, and after infection by blood transfusion clinical symptoms have taken from 17 days to many months to become manifest.[262-265]

The spectrum of clinical disease is wide. *B. microti* may cause asymptomatic infection or present with a mild flu-like illness in most cases in people with normal immune and splenic function.[266] The cardinal manifestations are fever and hemolytic anemia. Splenectomy, old age, and immunosuppression, including HIV, may increase the risk for more severe clinical disease.[267-269] The disease may progress to adult respiratory distress syndrome (ARDS), disseminated intravascular coagulation, or renal failure.[262] Patients who have had a splenectomy should avoid exposure to ticks in forested areas where the disease is transmitted.

B. divergens in Europe predominantly causes symptomatic infection in people who have had a splenectomy.[270,271] Here, the case fatality rate is on the order of 50%. However, symptomatic disease does also occur in immunocompetent individuals.[272]

Patients present with high fever, often with chills and sweats, jaundice, fatigue, malaise, headache, arthralgia, and myalgia. Gastrointestinal disturbances are common, and people may complain of dark urine secondary to hemoglobinuria. In some cases, the disease progresses with respiratory failure secondary to ARDS, disseminated intravascular coagulation, and renal failure requiring the appropriate supportive care.[273] Such severe cases resemble severe malaria in nonimmune persons, and it has been suggested that the pathophysiology, like malaria, includes adhesion and sequestration of infected erythrocytes and the release of proinflammatory cytokines. These diseases may be confused with falciparum malaria, leptospirosis, or viral hepatitis.

Hematologic and Laboratory Features

The hematologic features of the disease are dominated by substantial intravascular hemolysis.[273] Physical examination shows pallor, jaundice, and mild hepatosplenomegaly.

The laboratory findings are those of a compensated intravascular hemolytic anemia and thus feature low hemoglobin and haptoglobin levels and increased reticulocyte count, serum lactate dehydrogenase, and hemoglobinuria and proteinuria. Moderate thrombocytopenia is common.[265,274] Electron microscopy suggests uninfected erythrocytes are damaged during infection and so likely to be cleared more rapidly than normally.[275] The white blood cell count is usually decreased with atypical lymphocytosis and occasional evidence of hemophagocytosis. However, leukocytosis may occur, particularly in *B. divergens* infections.

The direct Coombs test is frequently positive for both C3 components and IgG. Polyclonal hypergammaglobulinemia is seen, and levels of C3 and C4 are reduced in acute infection.[276] Liver function tests show raised indirect bilirubin and mildly raised transaminase levels.

Diagnosis

The blood films stained with Giemsa or Romanovsky stain show ring-like intraerythrocytic parasites. Morphology is variable, and ring, rod, and ameboid forms of *Babesia* parasites may be seen (Fig. 160-16).[277] Occasionally, multiple intraerythrocytic forms can be seen, linked to form a tetrad or colloquially "Maltese Cross." However, at low parasitemia, *Babesia* parasites may easily be mistaken for ring-stage forms of *P. falciparum*. Moreover, false-positive sightings of *Babesia* spp. may be due to platelets, nonspecific stain deposit overlying erythrocytes, or indeed other intraerythrocytic inclusions.

Parasitemias are variable, and in *B. microti* infections may be low or transient.[266] In symptomatic infection, parasitemias typically range from less than 1% to 10% and rarely much higher, more than 70%, in severe infections.

Low-level parasitemias may be detected by inoculation of the blood into susceptible animals, including the golden hamster *(Mesocricetus auratus),* but this is not routinely available.

An indirect fluorescent antibody test using crude antigen is available in the United States through the Division of Parasitic Diseases at the Centers for Disease Control and Prevention (CDC).[278] Titers greater than 1:64 are regarded as positive and have been reported to be 88% to 96% sensitive and 90% to 100% specific.

PCR analysis is the most useful method of detecting or confirming low levels of parasitemia when serologic tests are positive, and it can also be used to monitor treatment.[279] Species-specific PCR primers are available to provide precise identification of infected parasites. Nevertheless, some rare forms of piroplasm parasites cannot be classified.

Treatment

Many *B. microti* infections are self-limiting, and therapy is used for moderate or severe disease.[280-282] The combination of atovaquone and azithromycin is the treatment of choice for mild-to-moderate illness, whereas clindamycin and quinine and exchange transfusion are indicated for severe disease.

B. divergens infections are often fatal in splenectomized patients, and therapy is based on somewhat limited experience. Pentamidine with cotrimoxazole has been used successfully, whereas individual patients treated with pentamidine and cotrimoxazole or quinine, chloroquine, and pyrimethamine have been unsuccessful. Three cases have been treated successfully with large-volume exchange transfusions (two to three blood volumes) and IV clindamycin and oral quinine.[283] This regimen of clindamycin and IV and oral quinine gives the best chance of success in the absence of randomized controlled trial evidence.

Exchange transfusion has been suggested as a useful adjunctive treatment if the parasitemia rises to greater than 10% and/or in severely ill patients. *B. divergens* infections can run a rapidly progressive course, and early exchange transfusion should be considered. A prolonged course of treatment may be required in immunocompromised patients.[284]

The parasite and hemoglobin levels should be regularly monitored during treatment.

Serologic testing and PCR testing of seropositive cases may be helpful in making a diagnosis. An indirect IFAT is available for *B. divergens* and *B. microti*. The IFAT titer is usually greater than 1:64 in acute infection. The reported sensitivity of the *B. microti* IFAT is 88% to 96% and specificity 90% to 100%.[278] Antimalarial antibodies may cross-react in this test.

Babesia and Transfusion-Transmitted Infection

Babesia infection poses a substantial and increasing threat to the blood supply. Between 150 and 170 cases of transfusion-transmitted babesiosis have been reported from 1979 to 2009 with 12 recorded fatalities.[285-287] There are no approved serologic screening tests for donors, and prevention of transfusion-transmitted babesiosis in the United States requires screening donors about a previous history of babesiosis and excluding patients with fever and a low hematocrit level. The scale of infection can be gauged from surveys of blood donors in the northeastern United States, where 1% to 2% of donors in some panels are seropositive for babesia.[288] In the United Kingdom, a conservative approach has been taken, and all donors who have

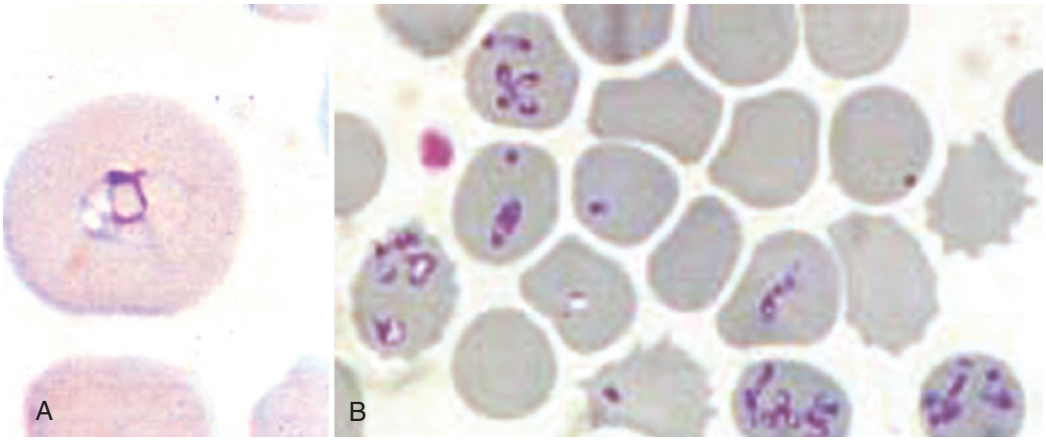

Figure 160-16 *BABESIA* PARASITES. Human infection with species of piroplasm transmitted by the bite of the tick *Ixodes ricinus* infected from cattle is a rare occurrence. Infection in normal people with this piroplasm may give rise to a self-limiting fever and parasitemia, as in the case of infection with the rodent parasite *Babesia microti* on the northeastern seaboard of the United States via the tick *Ixodes scapularis* **(A)**. Heavy red-cell infection may develop, however, in splenectomized patients, leading to fatal hemolytic anemia. This patient died of an infection acquired from the cattle parasite *Babesia divergens* in Scotland **(B)**. Other species of *Babesia* that occasionally infect humans, for example, the WA1, CA1, and MO1 isolates from the United States, are distinguished by molecular means.

visited the northeastern United States between May and October are excluded, in addition to the standard criteria of screening out febrile and/or anemic donors.

EOSINOPHILIA

Eosinophilia may be caused by a wide variety of systemic diseases and parasitic infections. The association with parasitic disease is through part of the Th2 T-cell response stimulated by helminths (worms), filaria, and cestodes. In general, protozoan infections, such as malaria, amebiasis, and giardiasis, are not associated with eosinophilia. However, case reports do exist suggesting isosporosis, toxoplasmosis, and infection with *Dientamoeba fragilis* can cause eosinophilia.

The rise in absolute eosinophil count depends on the degree of tissue invasion and is therefore modest with tapeworms and adult roundworms resident in the bowel but much higher where invasion occurs, for example, *Toxocara canis* or filaria. Some parasites have migratory larval stages, for example, ascariasis (roundworms) and clonorchiasis.

The differential diagnosis of eosinophilia in those who have lived in tropical areas is therefore wide. Evaluating the patients must begin by establishing the degree of eosinophilia (minimal, $<1 \times 10^9$/L; moderate, 1 to 3×10^9/L; high, $>3 \times 10^9$/L), the relation to travel (where necessary), and the presence of symptoms. A wide range of systemic diseases are associated with eosinophilia, and the eosinophil count may be high in drug allergy, pulmonary infiltrate with eosinophilia, and vasculitides.

Eosinophilia in Travelers

Evaluating the cause of eosinophilia in travelers to tropical areas where many parasitic diseases are endemic requires a systematic approach to narrow down likely possibilities by considering existing systemic diseases that may cause eosinophilia (particularly allergy, drug ingestion and autoimmune disease, vasculitis, or arthritis), the areas visited, duration of stay and history of exposure to soil-transmitted nematodes, freshwater potentially infected with schistosomiasis, and rural areas where loiasis, onchocerciasis, and hydatid disease may be contracted.

Physical examination may show subcutaneous swellings associated with filaria or hepatosplenomegaly consistent with schistosomiasis, hydatid disease, or toxocara.

Laboratory examination requires a stepwise approach given the breadth of the differential diagnosis (Table 160-4). The details of specific parasitologic tests are beyond the scope of this chapter, and detailed investigation would certainly require consultation with colleagues in infectious diseases.

Some parasitic causes of eosinophilia may not be diagnosed during the incubation period because larval stages of nematode worms may cause eosinophilic drug migration, but eggs will not be excreted in stools for many months. Moreover, filarial infections do not produce detectable parasites in blood or skin for many months after exposure.

In immunocompromised patients or those about to receive diagnosis, eosinophilia may be crucial, given the risks of giving immunosuppressive therapy such as chemotherapy or hematopoietic stem cell or solid organ transplantation to a patient with a chronic parasitologic infection. Patients with undiagnosed eosinophilia and possible exposure to *Strongyloides* should be given empirical course of treatment.

OTHER PARASITIC DISEASES

Many parasitic diseases cause some minor hematologic disturbance. A few may present with distinct hematologic features or indeed syndromes.

Table 160-4 Approach to Investigation of Eosinophilia in a Returning Traveler

History	Allergy Drugs and vitamins (L-tryptophan) Regions, localities, and duration of exposure
Physical examination	Skin, subcutaneous tissues Liver/spleen Signs of other systemic disease
Initial investigations	Full blood count and differential white blood cell count Stool examination for ova and parasites (×3) Urine analysis Examination of midday urine for ova and parasites (×3) (in those who have traveled to Africa or the Middle East)
Further investigations as suggested by travel and exposure from history	As suggested by travel and exposure from history *Strongyloides* culture and serologic testing Duodenal aspirate (strongyloidiasis, hookworm) Serologic testing (schistosomiasis, filariasis) Day/night blood films (filariasis)
Further studies if suggested by history and physical examination	Skin snips (onchocerciasis) Chest x-ray examination (hydatid cyst, tropical pulmonary eosinophilia, paragonimiasis) Soft tissue x-ray examination (cysticercosis) Sputum examination for ova and parasites (paragonimiasis) Abdominal ultrasound examination (hydatid cyst) Cystoscopy with or without biopsy (schistosomiasis) Rectal snips (schistosomiasis)

Filariasis

Lymphatic filariasis is caused by *Wuchereria bancrofti* and *Brugia malayi*. Infection with *W. bancrofti* occurs throughout the tropics, but by far the majority of cases are in Asia. The distribution of *B. malayi* is more restricted to China, Southeast Asia, and Southern India. The male and female adult worms live in the lymphatics, and the female worm releases a vast number of microfilariae, each 250 to 300 μm in length. Microfilariae develop but do not appear to multiply in the mosquito.

Infection may present with lymphangitis; often recurrent and unlike bacterial infections, the inflammatory features may spread distally. Over time, lymphatic obstruction may cause hydrocele, lymphedema (if severe elephantiasis), chyluria, and tropical pulmonary eosinophilia. *B. malayi* causes neither hydrocele nor chyluria.

Filariasis is most easily diagnosed by finding microfilariae in peripheral blood in a wet preparation. Motile microfilariae can be seen under low power and may be concentrated by centrifugation or filtration using a 3-μm filter. They are speciated in thin or thick films by their nuclear distribution and sheath characteristics (Fig. 160-17), and the two pathogenic species must be distinguished from the nonpathogenic species *Mansonella perstans* and *Mansonella ozzardi,* which do not have sheaths. Circulating *W. bancrofti* antigens can also be detected in the circulation by ELISA or immunochromatographic methods. Adult worms can sometimes be imaged by ultrasound. Filarial DNA from all species can be detected by PCR. Serologic testing is unhelpful because many people become exposed without developing clinical symptoms.

The worms cause marked or severe eosinophilia (see later) with counts greater than 1×10^9/L. Migration of worms through the lungs may exacerbate the eosinophil count and cause minor respiratory

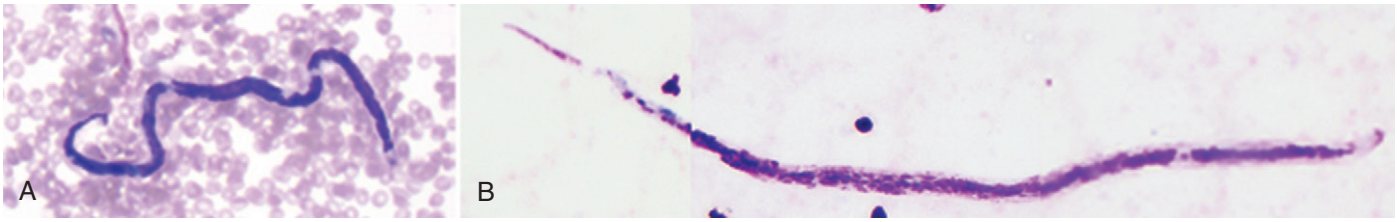

Figure 160-17 MICROFILARIA *(BRUGIA MALAYI)* ON THICK **(A)** AND THIN PREP **(B)**. The species is determined by the nuclear distribution and sheath characteristics.

symptoms and fluctuating radiologic signs. Other causes of tropical pulmonary eosinophilia are the worms (helminths) *Ascaris, Strongyloides, Schistosoma,* and *Toxocara.* Of these organisms causing pulmonary symptoms and signs, filariasis alone is responsive to diethylcarbamazine. Albendazole and ivermectin may also be used against filarial infection.

Toxoplasmosis

Toxoplasmosis may cause a mild illness or a more prolonged course with constitutional symptoms, atypical lymphocytes, and thrombocytopenia. Congenital toxoplasmosis as a result of infection acquired during pregnancy is a cause of neonatal thrombocytopenia, where it may be accompanied by cerebral calcification, hepatitis, and pneumonitis. In immunocompromised patients, new or reactivated toxoplasmosis may cause severe disease, including encephalitis, pneumonitis, and hepatitis. Thrombocytopenia is frequently accompanied by anemia and leukopenia.

Amebiasis

Amebiasis causes hypochromic, microcytic anemia both as a result of chronic blood loss and as an anemia of chronic disease in which disease progresses to formation of a liver abscess. Neutrophilia accompanies severe tissue damage caused by perforation of the bowel or a liver abscess or may be present in a secondary bacterial infection. Sometimes a leukemoid reaction with high white blood cell count and extreme left-shifted myeloid cells can be seen. Prolonged and/or extensive liver damage may cause prolongation of the prothrombin time.

Giardiasis

Acute giardiasis causes folate deficiency through malabsorption of folate in the small intestine. Chronic infection can cause vitamin B_{12} deficiency because ileal absorption of the vitamin is impaired.

Hookworm Infection

Adult hookworms attach themselves to the lining of the small bowel and take blood meals. The accumulated blood loss may be extensive because worms consume 2.0 mL *(Necator americanus)* or 0.5 mL of blood *(Ancylostoma duodenale)* each day. These infections are a common contributing factor to iron deficiency anemia in children, in whom infection is acquired by eating or walking barefoot on larva-infected soil. The disease is usually diagnosed by finding excreted eggs in stool samples, and treatment is with albendazole.

Tapeworm Infection

The fish tapeworm *(Diphyllobothrium latum)* is a rare cause of vitamin B_{12} deficiency. This tapeworm is transmitted in the Far East by eating raw or partially cooked fish. Infection has to be extensive and causes vitamin B_{12} deficiency; however, such cases are rare, even in endemic areas.

Schistosomiasis

Schistosoma haematobium causes blood loss in urine. Infection is acquired by swimming in freshwater, where cercariae from the infected snail host enter the skin and migrate to the blood vessels of the bladder. Chronic blood loss is a cause of iron deficiency anemia in children in endemic areas, but infection is likely to be diagnosed at an early stage in travelers because of the striking symptoms of painless hematuria. Treatment is with praziquantel.

FUTURE DIRECTIONS

Parasitic diseases present many problems for global heath. They cause a wide spectrum of hematologic abnormalities, and in endemic areas, a broad knowledge of the parasitic disease is vital for everyday practice. In nonendemic areas, there are a few situations where the diagnosis or management of these diseases may fall within the remit of hematologists and hematology laboratories, particularly malaria and the diagnosis of anemia, cytopenias, eosinophilia, and hepatosplenomegaly. Here, a high index of suspicion is often needed for the diagnosis to be made. A good travel history is crucial in order to establish exposure to parasitic disease and to prompt the search for the appropriate organisms. Several parasitic diseases pose a threat for the safe supply of blood, and the problems of screening of these infections are far from solved. Beyond everyday practice the pathophysiology and prevention of these diseases pose major challenges for biomedical research and public health.

CHAPTER 161

HEMATOLOGIC PROBLEMS IN THE SURGICAL PATIENT: BLEEDING AND THROMBOSIS

Mark T. Reding and Nigel S. Key

Surgical patients often present unique challenges to the consulting hematologist. They may develop hemostatic disorders ranging from unexpected bleeding to pathologic thrombosis, both of which can be potentially life-threatening. Consultation may be sought to assess preoperative bleeding risk and/or to recommend strategies to prevent postoperative thrombosis. The hematologist may be called upon to assist in the management of patients with a previous history of bleeding or thrombosis and in those with unexplained bleeding or thrombosis in the postoperative period. This chapter will review the preoperative evaluation of bleeding risk, the management of patients with hemostatic abnormalities, perioperative management of patients on long-term oral anticoagulation, and strategies to prevent surgery-induced venous thromboembolism (VTE).

PREOPERATIVE EVALUATION OF HEMOSTATIC RISK

Preoperative evaluation of hemostatic risk begins with a carefully taken history. Particular attention should be directed at specific bleeding symptoms and any history of bleeding associated with surgical procedures, including circumcision, tonsillectomy, and dental extractions. For women, it is important to inquire about a history of menorrhagia or excessive bleeding associated with childbirth. A detailed family history and record of medication use, including nonprescription medications, should be obtained. In adults, an interview to assess for the presence or absence of bleeding symptoms has a high discriminating power when used in a screening situation, where no bleeding disorder is suspected, but may be less discriminatory for those referred for specialty evaluation.[1] In the pediatric population, the medical history may be less reliable as a screening method because of fewer previous hemostatic challenges.[2]

Obtaining an adequate bleeding history may be complicated by the fact that many hemostatically normal people consider their bleeding to be excessive. Surveys of healthy individuals frequently report excessive nosebleeds (5% to 39%), gingival bleeding (7% to 51%), easy bruising (12% to 24%), menorrhagia (23% to 44%), postpartum bleeding (6% to 23%), and bleeding following dental extraction (up to 13%) and tonsillectomy (up to 11%).[1,3-5] Thus a thorough search for objective confirmation of reported symptoms is essential. Also, a constellation of bleeding symptoms, rather than any single symptom, is most helpful in suggesting the presence and etiology of an underlying bleeding disorder.

The need for routine coagulation testing before surgical or invasive procedures has been controversial for many years. Those in favor of testing point to the asymptomatic nature of some hemostatic abnormalities that may cause surgical bleeding and the occasional failure to obtain a detailed history.[6-8] A prospective study of preoperative screening in children before tonsillectomy found both history and laboratory screening to have high specificity but a low positive predictive value for perioperative bleeding.[7] Another study found that perioperative blood loss in adult cardiothoracic surgery patients could be predicted with a model, which included the bleeding time, prothrombin time (PT), and platelet count.[9] Given the variety of potential hemostatic defects, however, no simple screening system will identify all patients at increased risk for bleeding. Those against routine laboratory testing[10] point to retrospective studies indicating that they rarely detect unexpected bleeding disorders[11,12] and also emphasize the problems in evaluating false-positive abnormalities. A literature review found insufficient evidence to conclude that an abnormal prothrombin time/international normalized ratio (PT/INR) predicts bleeding during invasive procedures.[13] A retrospective review[14] of the value of preoperative platelet count, PT, and activated partial thromboplastin time (aPTT) in 828 patients undergoing major noncardiac surgery found that only 2% had abnormal results, and most were expected on the basis of history and physical examination. Furthermore, no relation between abnormal laboratory test results and intraoperative blood loss or postoperative bleeding complications was found.[14] This is not surprising, given the lack of studies using an evidence-based approach to determine the degree of abnormality in the PT/INR or aPTT at which an invasive procedure may be unsafe.[15] A number of prospective studies have also concluded that routine laboratory screening tests in asymptomatic patients are not predictive of perioperative or postoperative bleeding.[16-20] Thus for an unselected population, in the absence of historical risk factors or physical examination findings suggestive of an underlying bleeding tendency, the likelihood of an unsuspected, clinically significant congenital or acquired coagulopathy is low enough that routine laboratory screening is not warranted,[21] particularly for those undergoing low-risk procedures. The British Committee for Standards in Haematology recently issued guidelines reiterating this position: indiscriminate coagulation testing before surgical or invasive procedures is a poor predictor of bleeding risk and is not recommended in the absence of a positive personal or family bleeding history.[22] However, it has been suggested that Ashkenazi Jews should receive special consideration, because of the relatively high prevalence of factor XI deficiency. In this population, a screening aPTT might be reasonable.[21]

There are a variety of reasons why routine coagulation tests such as the PT/INR and aPTT may be poorly predictive of underlying coagulopathy and bleeding risk.[22] First, these tests are designed to measure time to clot formation in an artificial in vitro assay and may not reliably depict the global hemostatic situation in vivo (see Liver Disease). More importantly, the PT/INR and aPTT may be insensitive to mild but clinically relevant bleeding disorders such as von Willebrand disease or mild hemophilia. Conversely, they may detect conditions such as factor XII deficiency or a lupus inhibitor that do not increase the risk for bleeding.

The bleeding time had long been used to assess primary hemostasis and to predict the risk for hemorrhage associated with invasive procedures. However, there is now general consensus that in the absence of a history of a bleeding disorder, the bleeding time is not useful,[23] and many laboratories no longer perform this test. The platelet function analyzer (PFA-100) has been developed for rapid, quantitative, in vitro global testing of platelet function.[24-28] The clinical sensitivity (94% to 95%) and specificity (88% to 89%) of this instrument are virtually identical to platelet aggregometery,[28] and it is clearly superior to the bleeding time.[25,29] Although some have suggested that the PFA-100 could be used for screening for primary hemostatic defects,[30] such testing has limitations. The PFA-100 has high sensitivity for moderate to severe von Willebrand disease and

severe platelet defects, such as Glanzmann thrombasthenia and Bernard-Soulier syndrome, but it has poor sensitivity for milder intrinsic platelet disorders like storage pool disease, Hermansky-Pudlak syndrome, and primary secretion defects.[29] Although the PFA-100 is most useful when a hemostatic defect is clinically likely, in such cases additional testing is usually necessary to establish a specific diagnosis.[29-31] If clinical suspicion is high, further testing is indicated even with normal PFA-100 results.[29] Thus the PFA-100 should not be used for general unselected screening.[31] It had been hoped that platelet function testing of this sort might provide a convenient and inexpensive means to reliably predict surgical bleeding, but clinical studies have yielded disappointing results. Although some studies have demonstrated the ability of the PFA-100 to predict recurrent ischemic events following percutaneous coronary interventions[32] and coronary artery bypass graft surgery,[33] such testing has been inadequate to predict bleeding events following coronary stent placement.[34] Similarly, PFA-100 testing has not proven useful in predicting perioperative bleeding in patients undergoing heart surgery[35,36] or hip fracture surgery.[37]

Notwithstanding the ongoing controversy regarding the value of preoperative laboratory screening, it seems reasonable to adopt an approach that is a compromise, in which the level of hemostatic risk for the proposed surgery or invasive procedure (Table 161-1) forms the basis for an approach to preoperative evaluation (Table 161-2). A hemostatic history should be obtained in all patients, and in those about to undergo a low-risk procedure no laboratory tests are required. For moderate- to high-risk procedures, additional screening could include a PT/INR, aPTT, and assessment of the platelet count.

In practice, a hematologist is rarely consulted for routine screening because surgeons have adopted approaches based on their own training and local practice patterns. Rather, consultation is sought because of a history suggesting a bleeding disorder or an abnormal test result that is found on screening. The approach of the consultant cannot be one of "routine screening" because the judgment of the referring physician that a bleeding disorder may be present indicates an increased probability of finding an abnormality. If a referral is obtained as a result of an abnormal screening test result, this finding must be pursued and the abnormality fully explained. However, for all referrals the history is still of central importance and must include a thorough review of any bleeding episodes, including hospital records and results of prior hemostatic testing, as well as careful attention to the family history. The physical examination should focus on evidence of bleeding and on identifying systemic disorders such as hepatic or renal disease. If the history of bleeding is negative or minimal, appropriate laboratory testing would include a PT/INR, aPTT, and a biochemical profile to evaluate hepatic and renal function. A complete blood count and examination of the peripheral blood smear are useful to identify myeloproliferative disorders, gray platelet syndrome, or thrombocytopenia. If the history is suggestive of a hemostatic abnormality, a full evaluation is indicated and additional specific testing is usually required because von Willebrand disease; mild deficiencies of factors VIII, IX, and XI; severe factor XIII deficiency; platelet function defects; and fibrinolytic abnormalities may not be identified by global screening tests (see Table 161-2).

Table 161-1 Risk for Bleeding With Surgical or Invasive Procedures

Risk	Type of Procedure	Examples
Low	Nonvital organs involved, exposed surgical site, limited dissection	Lymph node biopsy, dental extraction, cataract extraction, most cutaneous surgery, laparoscopic procedures, coronary angiography
Moderate	Vital organs involved, deep or extensive dissection	Laparotomy, thoracotomy, mastectomy, major orthopedic surgery, pacemaker insertion
High	Bleeding likely to compromise surgical result, bleeding complications frequent	Neurosurgery, ophthalmic surgery, cardiopulmonary bypass, prostatectomy or bladder surgery, major vascular surgery, renal biopsy, bowel polypectomy

Table 161-2 Preoperative Hemostatic Evaluation

Routine Screening	
Surgical Risk	***Approach***
Low	History only
Moderate or high	History, PT, aPTT, platelet count
Consultation History	
Negative or minimal for bleeding	PT, aPTT, platelet count, biochemical profile, complete blood count with differential, review of peripheral smear
Suggestive of bleeding disorder	Add to above as indicated: platelet function tests, von Willebrand antigen, ristocetin cofactor, factor VIII, factor IX, factor XI, factor XIII assays

aPTT, Activated partial thromboplastin time; *PT,* prothrombin time.

HEMOSTATIC AGENTS

A variety of hemostatic agents are available and may be useful for the prevention or treatment of bleeding in the surgical patient. These agents work through a variety of mechanisms to facilitate hemostasis, including enhancement of primary hemostasis, stimulation of thrombin generation and fibrin formation, and inhibition of fibrinolysis.[38] However, it is important to note that there is a paucity of safety data involving hemostatic agents, because most trials have been designed to assess therapeutic efficacy rather than potential complications, including thrombosis.[38,39] The use of desmopressin, topical hemostatic agents, antifibrinolytics, and recombinant factor VIIa (rFVIIa) will be discussed here. Blood products (platelets, fresh frozen plasma, cryoprecipitate) and clotting factor VIII and IX concentrates are discussed elsewhere (see Chapters 118 and 137).

Desmopressin

Desmopressin (1-deamino-8-D-arginine vasopressin, or DDAVP) is a synthetic analogue of the antidiuretic hormone arginine vasopressin. Intravenous, subcutaneous, or intranasal administration of DDAVP results in transient increases in plasma concentrations of factor VIII and von Willebrand factor as a result of their release from vascular endothelium.[40] Peak levels (typically two to four times basal) are achieved 30 to 60 minutes after intravenous and 60 to 90 minutes after subcutaneous or intranasal administration.[41] Doses may be repeated at intervals of 12 to 24 hours, but tachyphylaxis may occur after three or four doses,[42] limiting further usefulness of DDAVP. Expression of glycoprotein Ib (GPIb) and GPIIb/IIIa on platelet membranes is also enhanced following administration of DDAVP.[43]

DDAVP is the treatment of choice for patients with mild hemophilia A or type 1 von Willebrand disease who require low-risk surgical procedures. Moderate- or high-risk procedures usually require administration of clotting factor concentrates.[42] DDAVP may also be useful for patients with congenital or acquired platelet function disorders.[41,43,44] A recent prospective, randomized, controlled trial comparing intranasal DDAVP with transfusion of fresh frozen plasma and/or platelets in cirrhotic patients with platelet counts of 30,000

to 50,000/μL and/or INRs of 2.0 to 3.0 undergoing dental extraction found that DDAVP was equally effective, less expensive, and well tolerated.[45]

Although initially felt to be promising,[46] the efficacy of DDAVP in reducing blood loss and transfusion requirements associated with cardiopulmonary bypass has not been supported by subsequent clinical trials[47-50] or metaanalyses.[51,52] Worrisome also is the fact that meta-analysis has shown a 2.4-fold increase in perioperative myocardial infarction in cardiac surgery patients treated with DDAVP.[52] Thus the routine use of DDAVP in cardiac, orthopedic, or other elective surgical procedures generally has not been recommended.[39,53] A more recent metaanalysis of 38 randomized placebo-controlled trials including nearly 2500 surgical patients found that DDAVP slightly reduced blood loss (approximately 80 mL per patient) and transfusion requirements (approximately 0.3 units per patient) without a reduction in the proportion of patients receiving transfusions.[54] The authors acknowledge that the clinical impact of this finding may be questioned yet still should be considered in view of the low cost of DDAVP. They found a similar incidence of thromboembolic events (5.4% versus 4.6%) in the DDAVP and placebo groups, respectively, but point out that identification of harm from DDAVP is limited by study design and that safety concerns remain unresolved.[54] However, certain subgroups of patients, such as those with platelet dysfunction, may benefit.[43,53-57] Because of the small but important risk for myocardial infarction,[58] DDAVP should be used with caution in any surgical patient with a history of, or risk factors for, coronary artery disease.

Topical Hemostatic Agents

Although some forms of topical hemostatic agents have been in routine clinical use for many years, a sharp increase in the number of available products has occurred over the last decade. These agents have found broad application across a wide range of surgical specialties, including cardiovascular, orthopedic, urologic, hepatic, reconstructive, laparoscopic, bariatric, and dental surgery.[59-62]

Choice of one topical hemostatic agent over another depends largely on individual experience and product availability.[63] There are few randomized controlled trials in the literature to guide clinical practice, and the methodologic quality of the available studies has been criticized.[39,64] The fact that many of the published studies in this field are industry funded further contributes to the lack of a solid evidence base from which clinical practice guidelines can emerge.[63]

Topical hemostatic agents can be grouped into several categories: physical agents (bone wax, Ostene), absorbable agents (gelatin foams, oxidized cellulose, microfibrillar collagen), biologic agents (thrombin, fibrin sealants, platelet gel), synthetic agents (polyethylene glycol hydrogels, cyanoacrylates, glutaraldehyde cross-linked albumin), and hemostatic dressings.[65] A brief overview of the different types of topical hemostatic agents follows. A thorough discussion of the currently available products, including mechanisms of action, specific advantages and disadvantages, and recommendations for use is provided in a recent comprehensive review.[65]

Physical Agents

Bone wax (first used in the 1880s) and alkylene oxide copolymers (Ostene, introduced in 2001) control hemorrhage by occluding bleeding channels on bone surfaces. The latter is preferred because it does not impede bone growth and is eventually absorbed. Both can increase the risk for local infection.[65]

Absorbable Agents

Gelatin foams, which have been in use since 1945, are derived from animal products and provide a physical matrix upon which coagulation can initiate. These products expand to double their volume, an attractive feature for use in penetrating wounds, but potentially problematic if used near nerves or in confined spaces.[65]

Oxidized cellulose was also introduced in the 1940s, and is derived from wood pulp. It provides a physical matrix for clotting initiation and has excellent handling characteristics. By lowering surrounding pH, oxidized cellulose exerts antimicrobial effect, but this property limits its ability to be used with biologic agents such as thrombin that are pH sensitive, and it can also contribute to local inflammation.[65]

Microfibrillar collagen was developed in 1970 and is derived from bovine components. It contributes to hemostasis through platelet adherence and activation and is effective in controlling wide-area parenchymal bleeding. Therefore it can be useful even in the face of heparin therapy, although it is less effective in the setting of thrombocytopenia.[65]

Biologic Agents

Thrombin derived from bovine plasma has been used for more than 40 years as a topical hemostatic agent in surgical patients. However, bovine thrombin can trigger the formation of antibodies that cross-react with human blood proteins, leading to hemorrhagic complications.[66-68] Because of these issues, human plasma–derived and subsequently recombinant forms of thrombin were developed. A phase III randomized double-blind comparative trial found that recombinant human thrombin had comparable efficacy and safety, but with fewer immunologic complications compared with bovine thrombin.[69] In 2008, recombinant human thrombin was licensed in the United States and is now the preferred form of topical thrombin.

Fibrin sealants are topical hemostatic agents composed of purified virally inactivated human fibrinogen, human thrombin, and sometimes added components such as human factor XIII and antifibrinolytic agents.[60] They have been available in Europe and Japan since the 1960s, but concern about viral transmission halted development and use of fibrin sealants in the United States until 1998, when licensing was approved by the Food and Drug Administration (FDA). The components of fibrin sealants are supplied in separate chambers of a dual-syringe delivery device that combines them at the time of administration. The final steps of the coagulation cascade are reproduced, resulting in formation of a stable fibrin clot. These products are particularly effective for controlling oozing from raw surfaces.[65]

Approved by the FDA in 2000, platelet gel combines microfibrillar collagen and thrombin with patient-derived plasma that contains fibrinogen and platelets. It is also applied with a dual-chamber syringe device, similar to fibrin sealants. The presence of platelets improves clot strength and provides growth factors, but the need for centrifugation of patient blood and processing before use are disadvantages.[65]

Synthetic Agents

Cyanoacrylates are liquid monomers that rapidly polymerize in the presence of water and attach adjacent surfaces together. Approved in the United States in 1998, octyl-2-cyanoacrylate is useful for closing small wounds or incisions and provides good cosmetic results.[65]

Polyethylene glycol hydrogel was approved for use in the United States in 2001 and can be sprayed onto tissue, where it rapidly forms a cross-linked polymer matrix and serves as a sealant and inhibits cell ingrowth and adhesion formation. It is useful for preventing pericardial adhesions and as a mechanical sealant for vascular reconstructions in which swelling and expansion are not a concern.[65]

Glutaraldehyde cross-linked albumin (bovine) received FDA approval in 1999. It has a rapid onset of action and is primarily used to seal sutures or staple lines in complex cardiovascular procedures. However, it can restrict tissue growth and should therefore not be used circumferentially around developing structures, particularly in children.[65]

Hemostatic Dressings

Progress in the field of topical hemostatic agents over the last decade has expanded into the development of hemostatic dressings. Several products containing combinations of gauze and lyophilized fibrinogen and thrombin, chitin and chitosan (polysaccharides found in arthropod skeletons and produced by fermenting algae), and mineral zeolite are available. In general, the use of hemostatic dressings is still under investigation, primarily by the military and emergency first responders.[65]

Antifibrinolytics

Antifibrinolytic agents include the synthetic lysine analogues 6-aminohexanoic acid (aminocaproic acid) and 4-(aminomethyl) cyclohexanecarboxylic acid (tranexamic acid), and the serine protease inhibitor aprotinin. Although both types of antifibrinolytic agents have been used in managing surgical bleeding, the lysine analogues are available in oral forms that facilitate their use in other clinical situations as well.

Aminocaproic Acid and Tranexamic Acid

Both aminocaproic acid and tranexamic acid bind reversibly to the lysine binding site on plasminogen, thereby interfering with fibrin binding, which is required for activation by plasminogen activators.[41] Although tranexamic acid is approximately 10 times more potent than aminocaproic acid and has a longer half-life, both drugs have similar hemostatic effects even in the absence of laboratory signs of excessive fibrinolysis.[70] Extravascular accumulation with inhibition of tissue fibrinolysis and subsequent clot stabilization is thought to explain the efficacy of these drugs.[41]

Because the oral form of tranexamic acid was not commercially available in the United States for a number of years, aminocaproic acid became the lysine derivative of choice. It is commonly used to treat mucosal hemorrhage (menorrhagia, epistaxis, dental bleeding) in patients with congenital coagulopathies and is also effective for prevention of oral bleeding in those who require dental work while receiving long-term oral anticoagulant therapy. Although aminocaproic acid is sometimes used to treat bleeding in patients with thrombocytopenia, randomized controlled trials are lacking.[45] The use of antifibrinolytic drugs in patients with gastrointestinal bleeding would seem rational given the high concentration of fibrinolytic enzymes in the digestive tract, and a metaanalysis found reductions in recurrent bleeding, need for surgery, and mortality.[71] However, improvements in the efficacy of other medical and endoscopic treatments have limited the use of these drugs in this setting, although they are still useful for some patients with underlying bleeding disorders.[41] The urinary tract is also rich in plasminogen activators, and some clinical trials comparing tranexamic acid or aminocaproic acid with placebo in patients undergoing prostatectomy have shown reduced blood loss, but not a reduced need for transfusion or decreased mortality.[41] Additional data from appropriately designed clinical trials are needed before the routine use of antifibrinolytic agents in urologic surgery can be recommended.[56] As noted earlier, oral antifibrinolytics are effective in the treatment of menorrhagia, and oral tranexamic acid received FDA approval for this indication in late 2009.

The largest experience with aminocaproic acid in surgical patients is in those undergoing cardiac surgery. Older metaanalyses have consistently shown that prophylactic treatment of cardiac surgery patients with aminocaproic acid results in a 30% to 40% reduction in postoperative bleeding, without an increase in thromboembolic complications.[52,72-74] Similar results have been shown with tranexamic acid.[43] Other metaanalyses have shown that aminocaproic acid and tranexamic acid are effective in reducing surgical blood loss but have yielded inconsistent results in reducing transfusion requirements.[53,75] A wide variety of dosing schedules may partly explain these heterogeneous results.[53] A recent metaanalysis showed that both agents were effective in reducing blood loss and transfusion requirements in those undergoing cardiac surgery.[76]

A number of studies have demonstrated that antifibrinolytic agents reduce blood loss in orthopedic surgery. A metaanalysis of 43 randomized controlled trials in total hip and knee arthroplasty, spine fusion, musculoskeletal infection, or tumor surgery found that aprotinin and tranexamic acid significantly reduced the number of patients requiring transfusion, with a dose–effect relationship suggested for tranexamic acid.[77] Aminocaproic acid was not found to be effective, although the data were sparse. Similarly, data were too limited to make any definitive conclusions about the safety of these agents in orthopedic surgery patients. A recent metaanalysis of 11 clinical trials involving total hip replacement found that the use of tranexamic acid significantly reduced intraoperative blood loss and transfusion requirements, without any increase in venous thromboembolism or other complications.[78] A recent double-blind, randomized, placebo-controlled trial demonstrated that intraoperative treatment with tranexamic acid was also effective in reducing the need for transfusion in patients undergoing retropubic prostatectomy.[79]

Antifibrinolytics, particularly tranexamic acid, have also been studied in the treatment of trauma patients, in whom 30% of deaths are attributed to hemorrhage.[80] A recent landmark trial, Clinical Randomisation of an Antifibrinolytic in Significant Haemorrhage 2 (CRASH-2), evaluated the safety and efficacy of tranexamic acid in the setting of trauma.[81] This randomized, placebo-controlled, multinational trial that included more than 20,000 trauma patients demonstrated a significant reduction in all-cause mortality and death due to bleeding in the treatment group. More severely injured patients and those treated within 3 hours of injury derived the greatest benefit, and there was no difference in the rate of vascular occlusive events between the two groups.[81] A subsequent review has argued for the immediate incorporation of tranexamic acid into trauma clinical practice guidelines and treatment protocols given that it is the only drug with prospective clinical trial evidence to support this application.[82]

Two randomized controlled trials have shown that high-dose tranexamic acid significantly reduces surgical blood loss and transfusion requirements in liver transplant recipients.[83,84] A recent metaanalysis identified 23 studies with a total of 1407 liver transplant patients who received aminocaproic acid, tranexamic acid, or aprotinin compared with each other or with controls/placebo. This review found that tranexamic acid and aprotinin reduced transfusion requirements without any increased risk for hepatic artery thrombosis, VTE, or perioperative mortality.[85] Additional studies comparing the efficacy of tranexamic acid with aminocaproic acid and/or aprotinin are needed in this population.[44]

There are case reports of thrombosis associated with both aminocaproic acid and tranexamic acid. However, no significant increase in thrombotic complications has been observed when these drugs have been used in patients undergoing cardiac, liver transplant, or orthopedic surgery, although those studies were not specifically powered to evaluate for thrombotic complications.[42,44,77,79,86]

Aprotinin

Aprotinin is a polypeptide extracted from bovine lung that inhibits the action of serine proteases, including plasmin and kallikrein.[42] In addition to its antifibrinolytic activity, aprotinin is also thought to preserve platelet function and have antiinflammatory effects, both of which may be mediated by inhibition of protease-activated receptors expressed on platelets, vascular endothelium, and neutrophils.[86] The pharmacokinetics of aprotinin are complex, and there is wide between-patient variability.[54] Renal failure results in reduced clearance and prolonged half-life of this drug. Because neither the optimal dose nor the appropriate therapeutic concentration required for effective hemostasis has been established, many different dosing regimens have been used.[54] Because of its bovine origin, aprotinin may cause

hypersensitivity reactions. The incidence is less than 1%, increasing to approximately 3% upon reexposure. Thus retreatment within 6 months is not recommended.[58,87]

The bulk of clinical experience with aprotinin is in cardiac surgery. A large number of clinical trials have consistently shown that prophylactic administration of aprotinin improves hemostasis and reduces requirements for transfusion of red blood cells, platelets, and fresh frozen plasma in the majority of patients undergoing cardiopulmonary bypass.[40,44,54] A large metaanalysis of randomized controlled trials using aprotinin in cardiac surgery also demonstrated decreased mortality and a reduced incidence of repeat thoracotomy, without any increased risk for perioperative myocardial infarction.[53] Furthermore, another metaanalysis of randomized controlled trials showed a lower incidence of stroke in cardiac surgery patients treated with high-dose aprotinin.[88]

Although there is abundant evidence that aprotinin reduces blood loss and transfusion requirements in cardiac surgery patients, recent literature highlights the risk for serious adverse events associated with this drug. A nonrandomized observational study involving 4374 patients who underwent elective coronary revascularization compared aprotinin, aminocaproic acid, and tranexamic acid with no treatment.[89] Aprotinin was associated with a doubling of the risk for renal failure requiring dialysis, a 55% increase in the risk for myocardial infarction or heart failure, and a nearly doubled increase in the risk for stroke or encephalopathy. Aminocaproic acid and tranexamic acid reduced blood loss to a similar degree, but without any increased risk for adverse renal, cardiac, or cerebrovascular events. The same investigators subsequently reported that aprotinin use is associated with an increased risk for long-term (5 years) mortality following coronary artery bypass graft surgery.[90] In another cohort study of 3348 patients who underwent cardiothoracic surgery in a single center that reserves aprotinin use for complex surgeries and for those patients whose religious beliefs forbid blood transfusion confirmed an increased risk for postoperative renal dysfunction but found no increased risk for myocardial or cerebrovascular events.[91] Although aminocaproic acid and tranexamic acid appear to be relatively safe, it is important to note that the numbers of trials and study participants are much smaller for these drugs than for aprotinin. Moreover, trials directly comparing aprotinin with aminocaproic acid and tranexamic acid have been few in number and small in size.

To address these issues, the Blood Conservation Using Antifibrinolytics in a Randomized Trial (BART) study was launched in 2002.[92] Over the subsequent 5 years, this blinded multicenter trial randomly assigned 2331 cardiac surgical patients to receive aprotinin, tranexamic acid, or aminocaproic acid during surgical procedures for which cardiopulmonary bypass was required. The study was terminated prematurely in October 2007 due to a higher death rate in the aprotinin group, and the drug was subsequently withdrawn from the market in both Europe and the United States. In the years following BART, debate has continued about the optimal use of antifibrinolytics in cardiac surgery. A 2009 metaanalysis of 49 trials involving over 7400 subjects found that, compared with placebo or no treatment, aprotinin, tranexamic acid, and aminocaproic acid were all effective in reducing the need for transfusion but that the risk for death was consistently higher with the use of aprotinin than with either of the lysine analogues.[93] In contrast, a 2010 multicenter database analysis of over 30,000 children undergoing congenital heart operations at 35 children's hospitals found no difference in postoperative mortality, need for dialysis, or length of stay in the 44% of total subjects who received aprotinin versus those who did not.[94] This study serves as a reminder that extrapolation from clinical trial data in adults may not be appropriate for the pediatric population.

A potentially important issue that may not have been adequately addressed in earlier trials of antifibrinolytic agents in cardiac surgery is the risk category of the patients being studied. Most studies in the literature are limited to coronary artery bypass graft patients, a generally low- to moderate-risk population. Although the BART study specifically aimed to include high-risk cases, complex or emergency surgeries were not included, leaving a population of predominantly low- or moderate-risk patients.[95] A recent single-center cohort study compared outcomes of 772 cardiac surgery patients who received aprotinin with the same number of propensity score–matched patients who received tranexamic acid and found that aprotinin was associated with lower massive blood loss and fewer adverse events in high-risk, but not in low- to moderate-risk patients.[96] This suggests that aprotinin, with its greater hemostatic potency and antiinflammatory properties, may be the antifibrinolytic agent of choice in high-risk patients, who tend to develop more severe coagulopathy and systemic inflammatory response syndrome.[96] Randomized controlled trials in high-risk cardiac surgery patients are needed to test this hypothesis.

In spite of the large number of studies and amount of effort put forth, debate remains about the optimal use of antifibrinolytic agents in cardiac surgery. There appears to be no appreciable difference in efficacy between tranexamic acid and aminocaproic acid, and most studies were not designed to properly evaluate safety. Aprotinin remains unavailable in 2012 but may have a role in high-risk patients. For now, clinical decisions about use of antifibrinolytic agents in this setting should be individualized based on anticipated blood loss and the risk characteristics of each patient.[96]

Although the use of aprotinin in orthotopic liver transplantation was first reported more than 20 years ago, its routine use in this setting has also been long debated. Two randomized controlled trials have shown a 30% to 40% reduction in transfusion requirements in liver transplant recipients.[97,98] Aprotinin may also have favorable hemodynamic effects following graft reperfusion,[99] possibly because of inhibition of the release of bradykinin and other vasodilating substances. More recently, a retrospective analysis of 150 patients from a single center who underwent liver transplant between 2004 and 2008 found that those who received prophylactic aprotinin (n = 111) required significantly fewer units of red blood cell transfusion than the group not treated with aprotinin (n = 39).[100] Comparative studies of antifibrinolytic agents in this setting are limited, but a similar study comparing 300 patients who received aprotinin and 100 patients who received tranexamic acid found no differences in intraoperative blood loss, transfusion requirements, renal function, and 1-year survival.[101] A 2011 Cochrane database review found that aprotinin may potentially reduce blood loss and transfusion requirements in liver transplantation, but methodologic shortcomings and high risk for bias in the available studies severely limit the strength of these conclusions.[102] Clearly, properly designed trials are needed to address these issues. Prophylactic administration of aprotinin has also been shown to significantly reduce perioperative bleeding in patients undergoing noncardiac thoracic surgery and orthopedic surgery, although the data are limited.[44,103]

Recombinant Factor VIIa

rFVIIa is a hemostatic agent currently licensed in the United States only for the prevention and treatment of bleeding in hemophilia patients with factor VIII or factor IX inhibitors, acquired hemophilia, and in those with congenital factor VII deficiency. This drug is believed to induce hemostasis at local sites of tissue injury through enhancement of thrombin generation on the surface of thrombin-activated platelets.[104] rFVIIa also activates thrombin activatable fibrinolysis inhibitor (TAFI), which in turn stabilizes the clot by inhibiting fibrinolysis.[105] The use of rFVIIa in the management of hemophilia and factor VII deficiency is reviewed in Chapters 138 and 139.

Following its approval by the FDA in 1999, encouraging anecdotal experience and case series generated much interest in the use of rFVIIa for a variety of off-license indications, such as to control refractory bleeding after surgery or major trauma and to prevent bleeding in surgeries where blood loss is expected to be excessive. A recently published retrospective database analysis found that from 2000 to 2008, the off-label use of rFVIIa in hospitals increased more than 140-fold. The most common off-label uses include trauma, adult and pediatric cardiovascular surgery, and intracranial hemorrhage.[106]

Difficult-to-control "coagulopathic" hemorrhage commonly occurs without preexisting coagulation deficits in those who suffer

major trauma, and roughly half of all early trauma deaths are due to hemorrhage. Such bleeding is typically multifactorial, with contributions from the dilution of platelets and clotting factors secondary to large-volume transfusions, excessive transfusion of citrate anticoagulant, hyperfibrinolysis, hypothermia with subsequent slowing of the enzymatic coagulation reactions, and acidosis. In 1999 a report of the successful treatment of a bleeding soldier with rFVIIa[107] generated widespread interest in the use of rFVIIa in areas other than hemophilia. A number of case reports and series followed, describing favorable results with the use of rFVIIa in trauma patients. A prospective, multicenter, randomized, controlled trial published in 2005[108] that included 143 blunt and 134 penetrating trauma patients found that in the group with blunt trauma, three successive doses of rFVIIa significantly decreased red blood cell transfusion (mean reduction of 2.6 units) and decreased by approximately half the number of patients requiring massive transfusion (more than 20 units of red blood cells). Although similar trends were observed in the patients with penetrating trauma, the differences were not statistically significant. In spite of the reduction in the need for blood products, there was no survival benefit. After these initial encouraging reports of the use of rFVIIa in trauma patients, questions regarding optimal dosing and timing of administration remained. In an attempt to address these issues, the Western Trauma Association Multi-Center Trials Group (with support from the drug manufacturer) conducted a case registry of 380 adult trauma patients who received rFVIIa as an adjunct for hemorrhage control in 21 level I and II U.S. trauma centers between 2003 and 2008.[109] This registry was unable to define the precise role of rFVIIa in traumatic bleeding. However, a pH of less than 7.2, platelet count of less than 100,000/μL, and blood pressure less than or equal to 90 mm Hg were each found to be predictors of poor response to rFVIIa, suggesting that correction of shock, acidosis, and thrombocytopenia should precede the use of rFVIIa in bleeding trauma patients.[109] The CONTROL trial is the largest placebo-controlled study of rFVIIa in trauma patients to date. This multicenter trial randomized 560 actively bleeding trauma patients and found no differences in overall mortality, organ system failure, or adverse events in either group.[110] Thus, although initial reports were encouraging, there is currently insufficient evidence to support a role for the routine use of rFVIIa in the setting of trauma.

The use of rFVIIa in cardiac surgery remains a topic of much debate, with a number of conflicting reports and opinions in the literature. Significant hemostatic alterations may result from cardiopulmonary bypass, leading to excessive postoperative bleeding. Hypothermia, hemodilution, and activation of the coagulation, fibrinolytic, and inflammatory pathways all contribute to the complex hemostatic defect associated with cardiopulmonary bypass. In addition, use of newer anticoagulant drugs, including direct thrombin inhibitors, low-molecular-weight heparins (LMWHs), pentasaccharides, and platelet inhibitors, may also contribute to hemorrhagic risk in cardiac surgery patients.[111] Conversely, by virtue of the disease process itself and the nature of the surgical procedures undertaken, cardiac surgery patients are also at risk for both arterial and venous thrombosis.[112] Because perioperative bleeding is a major cause of morbidity and mortality, there is increasing off-label use of rFVIIa in this patient population.[113] A number of case reports and uncontrolled case series in both adult and pediatric populations have suggested that rFVIIa is effective in decreasing blood loss and transfusion requirements in many patients with intractable bleeding following cardiopulmonary bypass. However, well-designed randomized placebo-controlled trials are lacking. Although a randomized placebo-controlled study in adult complex noncoronary cardiac surgical patients[114] found that rFVIIa significantly reduced the need for transfusion, the study has major methodologic limitations.[113] Another randomized placebo-controlled study using two different doses of rFVIIa found that it may be beneficial for treating bleeding after cardiac surgery but also noted an increase in the number of serious adverse events, including stroke.[115] Although use of rFVIIa in cardiac surgery patients has been increasingly common, there now appears to be general consensus that prophylactic or routine use is not warranted.[113,116,117]

Outside of trauma and cardiac surgery, rFVIIa has been used in a variety of other surgical settings, with conflicting results. A randomized, double-blind, placebo-controlled trial of 36 patients undergoing retropubic prostatectomy demonstrated a greater than 50% reduction in surgical blood loss in patients treated with a single intraoperative dose of rFVIIa.[118] Conversely, however, in a similarly designed trial in 204 noncirrhotic patients undergoing partial hepatectomy, treatment with rFVIIa resulted in only a modest reduction in blood loss.[119] In another study involving 221 noncirrhotic patients undergoing partial hepatectomy, the use of rFVIIa before and every 2 hours during surgery failed to decrease transfusion requirements or the number of patients needing transfusion.[120] Overall, the published experience with the use of rFVIIa in urologic, orthopedic, vascular, and obstetric/gynaecologic surgery is still too limited and subject to bias to draw meaningful conclusions.[114] High-quality clinical trials are needed but are unlikely to be performed.

Neurosurgical patients are distinct from other groups in that rather than treating massive hemorrhage, the goal is to treat relatively small bleeds within a closed space where even mild or modest benefit may result in significantly better outcomes.[114] A randomized placebo-controlled study of 399 patients with intracerebral hemorrhage showed that treatment with rFVIIa within 4 hours after the onset of symptoms limits growth of the hematoma, reduces mortality, and improves functional outcomes at 90 days, albeit with a small increase in the frequency of thromboembolic events.[121] However, the same investigators subsequently reported the results of a larger phase III trial (Factor Seven for Acute Hemorrhagic Stroke [FAST]) involving 821 patients. In this study, rFVIIa failed to improve the primary outcomes of mortality and disability at 90 days.[122] Following this, the manufacturer of rFVIIa abandoned plans to seek FDA approval for use in the treatment of acute intracranial hemorrhage.[123]

The primary safety concern with the use of rFVIIa is thrombosis. Most of the initially reported thrombotic events were associated with other risk factors such as preexisting atherosclerotic vascular disease or advanced age.[124] In hemophilia, the risk for thrombosis is estimated to be less than 1%.[125,126] However, with the increasing off-label use of rFVIIa, concerns about the thrombogenic potential of this drug have remained. Much of the published literature describing off-label use of rFVIIa reports a very low incidence of thrombotic complications, but it is important to recognize that most of these studies involved patients with already impaired coagulation and were not specifically designed to assess thrombotic risk. A 2006 review based on the FDA MedWatch database[127] heightened awareness about the thrombogenic potential of rFVIIa. Both arterial and venous thromboembolic events have been reported, and the vast majority have occurred with off-label use of rFVIIa. Thromboembolic events were the probable cause of death in 72% of the reported fatalities. Half of the thromboembolic events occurred within 24 hours of the last dose of rFVIIa, and many occurred within 2 hours.[128] Similar concerns were raised by a report describing a 9.4% incidence of thromboembolic complications after administration of rFVIIa to trauma patients, with 10 of 14 deaths attributed at least in part to the thromboembolic event.[128] A recently published systematic review and metaanalysis also concluded that off-label use of rFVIIa for intracranial hemorrhage and cardiac surgery is associated with an increased risk for thromboembolism.[118]

In summary, rFVIIa represents a major advance in the management of hemophilia A and B patients with inhibitors, acquired hemophilia, and congenital factor VII deficiency. The off-label use of this drug has been the subject of much debate, driven in part by its very high cost. Although rFVIIa was once touted as a "universal hemostatic agent,"[129] numerous clinical trials over the last decade have illustrated that it is more appropriately considered to be a potent but specific prohemostatic agent that requires the presence of adequate amounts of hemostatic substrates in order to be effective.[130] A 2011 Cochrane database review of 25 randomized controlled trials found that the use of rFVIIa, either therapeutically or prophylactically, in patients without hemophilia was of unproven effectiveness and recommended that the use of the drug outside its current licensed indications be restricted to clinical trials.[131]

MANAGEMENT OF PATIENTS WITH HEMOSTATIC ABNORMALITIES

Patients with known hemostatic abnormalities are often referred before surgery for assessment of bleeding risk and recommendations regarding perioperative management. The approach to these patients should be according to the following considerations: (1) evaluation of the risk for bleeding associated with the specific surgery or procedure (see Table 161-1); (2) careful consideration of the need for surgery and its urgency; greater risks are more warranted for correction of life-threatening conditions than for purely elective procedures; (3) recognition of the nature and severity of the patient's hemostatic abnormality and the ability to correct it; and (4) consideration of the duration of replacement that will be required, with appreciation of potential bleeding that may be associated with events in the postoperative period such as removal of sutures and deep drains and the need for physical therapy, especially after orthopedic surgery. The following sections discuss perioperative management of some common coagulation abnormalities; the management of congenital factor deficiencies and von Willebrand disease are discussed elsewhere in this text (see Chapters 137, 139, and 140).

Thrombocytopenia

Thrombocytopenia is one of the most common acquired hemostatic abnormalities, and the availability of platelet transfusion makes consideration of both emergency and elective surgery reasonable even in severely thrombocytopenic patients. The best index of bleeding risk in thrombocytopenic patients is the platelet count. In nonsurgical patients a threshold platelet count of 10,000/μL is widely used for prophylactic transfusions, yet there is inadequate scientific evidence to determine the platelet count below which the risk for surgical bleeding is increased.[132,133] The American Society of Anesthesiologists Task Force on Blood Component Therapy concluded that prophylactic platelet transfusion in surgical patients is usually indicated when the count is below 50,000/μL and is rarely indicated when the count is above 100,000/μL.[133] Clinical trials addressing this issue are still lacking.[134,135] For low-risk surgery, a single transfusion to increase the platelet count to more than 50,000/μL followed by close observation may suffice, whereas transfusion to maintain the platelet count at greater than 50,000/μL for moderate-risk surgery and greater than 100,000/μL for high-risk surgery is usually appropriate. The optimal duration of postoperative platelet support has not been carefully studied, but even for moderate- or high-risk surgery, platelets may be needed for less than 1 week because they are principally required for primary hemostasis. The platelet count should be monitored closely during the postoperative period, with the expectation that platelet survival will be shortened by infection, fever, or bleeding. In addition, platelet transfusion may be indicated for surgical patients despite an apparently adequate count in the presence of known or suspected platelet dysfunction and microvascular bleeding.

When thrombocytopenia is due to increased platelet destruction (e.g., immune thrombocytopenic purpura), prophylactic platelet transfusion is largely ineffective and is indicated only for active, serious bleeding. In preparation for surgery, therapy with steroids and/or intravenous γ-globulin often will increase the platelet count to a satisfactory level so that transfusion is not needed. Rh_o(D) immune globulin (WinRho) may also be useful in this setting.

Platelet Dysfunction

Patients with platelet dysfunction represent a large group for whom preoperative consultation is sought, typically because of an abnormal bleeding history or the discovery of a prolonged bleeding time or other laboratory assessment of platelet function with a normal platelet count. Drugs are the most common cause of acquired platelet dysfunction. Many commonly used types of medications, including aspirin and other nonsteroidal antiinflammatory drugs (NSAIDs), antibiotics, antidepressants (selective serotonin reuptake inhibitors), cardiovascular drugs, and newer antiplatelet agents, including adenosine diphosphate (ADP) receptor or GPIIb/IIIa antagonists, can cause platelet dysfunction. Ethanol as well as certain foods and herbal supplements can also inhibit platelets; a careful history is therefore essential. Any drugs that interfere with platelet function should be discontinued before surgery and avoided in the perioperative period if possible.

A number of medical conditions can cause acquired platelet dysfunction. The etiology may be fairly obvious in cases of renal or liver disease, myeloproliferative disorders, leukemias, myelodysplastic syndromes, or dysproteinemias, but consideration of undiagnosed intrinsic platelet defects (storage pool disease or platelet release defects) or von Willebrand disease may be necessary. Treatment of the underlying disease is the most effective approach, if possible. If not, platelet transfusion may be indicated, but the dose required to achieve hemostasis is difficult to predict and depends in part on the severity of the underlying platelet abnormality. As discussed earlier, treatment with DDAVP may be appropriate in selected patients. The exact mechanism of action of DDAVP in acquired platelet dysfunction is not well understood, but one study suggests that DDAVP interacts directly with platelets and exerts a priming effect on platelet aggregation stimulated by ADP or collagen.[136] Expression of GPIb and GPIIb/IIIa on platelet membranes is also enhanced following administration of DDAVP.[44]

Renal Disease

Impaired hemostasis has long been recognized in patients with chronic renal failure and is discussed in greater detail in Chapter 156. The pathogenesis is multifactorial but is due in large part to alterations in platelet function.[137] Anemia also contributes to platelet dysfunction in chronic renal failure. Red blood cells release ADP, which in turn inactivates vascular prostacyclin, an inhibitor of platelet function.[138] Correction of anemia, now routinely accomplished through the use of recombinant erythropoietin, also improves the rheologic factors that facilitate platelet interaction with the vessel wall. Increase in hematocrit, whether by the use of erythropoietin or transfusions, is accompanied by significant shortening of the bleeding time and improvement of platelet adhesion.[139] In addition to platelet dysfunction and altered balance between mediators of normal endothelial function, the pathophysiology of uremic bleeding is complicated by the comorbidities in this patient population, such as vascular disease and hypertension, and the medical treatment of those conditions.[140]

Owing to the success of erythropoietin, other hemostatic agents now play a smaller, yet still important, role in the management of bleeding in patients with renal insufficiency, particularly those with acute or subacute renal failure. DDAVP was shown in a randomized placebo-controlled trail to normalize bleeding times within 1 hour in uremic patients.[141] DDAVP may be useful for treating acute bleeding and for prophylaxis before biopsy or urgent surgery. Conjugated estrogens also improve bleeding times and reduce or stop bleeding in uremic patients through unknown mechanisms.[142,143] Unlike DDAVP, the clinical effect of conjugated estrogens is delayed for several hours, but they have a much longer duration of action (10 to 15 days).[42] Thus conjugated estrogens are more useful for management of chronic recurrent bleeding and perhaps before elective surgery. DDAVP and conjugated estrogens may be given concurrently, thereby taking advantage of the different timing of their hemostatic effects.[42] Conjugated estrogens may be given orally or intravenously, usually as five to seven daily doses, and are usually well tolerated, with negligible side effects. Cryoprecipitate can also shorten the bleeding time in patients with renal failure, but concerns about viral transmission and the effectiveness of other hemostatic agents have limited its routine use in this setting.

Liver Disease

Hemostatic alterations in patients with acute or chronic liver disease (see Chapter 155) are complex and involve both procoagulant and anticoagulant pathways.[144,145] Although patients with liver disease are typically felt to have deficient hemostasis, this concept has been challenged in the recent literature.[146] These patients are not "autoanticoagulated" as often assumed. In fact, they are not protected from and may even be at increased risk for thrombosis, particularly in the portal venous system.[147-151] The presence of genetic thrombophilic mutations may further increase this risk.[152] The procoagulant tendency associated with chronic liver disease[153-155] suggests that prophylaxis against venous thromboembolism may be warranted in high-risk situations.[147] However, the perceived bleeding risk often limits the use of prophylaxis,[156] and appropriately designed pharmacologic clinical studies are clearly needed here.[147]

The coagulopathy of liver disease is usually the result of a combination of several defects,[157,158] including the following: (1) There is reduced synthesis of procoagulant and anticoagulant clotting factors, which is proportional to the extent of hepatocyte damage.[158] Minimal prolongation of the PT/INR occurs in mild to moderate liver disease, primarily reflecting decreased factor VII synthesis, whereas more advanced liver disease can lead to reductions in factors II, IX, and X, followed by fibrinogen and factor V. Conversely, factor VIII levels are typically preserved (and are often elevated) even in severe liver disease. This is likely the result of decreased clearance of factor VIII, mediated by increased levels of von Willebrand factor and decreased expression of low-density lipoprotein receptor–related protein, both of which occur in advanced liver disease.[147] (2) Vitamin K deficiency due to impaired enterohepatic recirculation of bile salts and subsequent malabsorption may compound the reduction in clotting factor synthesis. (3) Dysfibrinogenemia due to synthesis of abnormally glycosylated fibrinogen occurs in 60% to 70% of patients with liver disease.[159] This results in a disproportionate prolongation of the thrombin time relative to a mildly prolonged PT/INR and aPTT. (4) Thrombocytopenia is common in advanced chronic liver disease and occurs in up to 65% of those with cirrhosis.[160,161] Platelet counts rarely fall below 30,000 to 40,000/μL, and spontaneous bleeding on this basis alone is uncommon. Thrombocytopenia results from both hypersplenism and reduced hepatic synthesis of thrombopoietin.[162] Ethanol toxicity and folate deficiency may also impair platelet production. (5) Platelet dysfunction through a variety of mechanisms is also seen in liver disease,[159] although this may be offset by elevated von Willebrand factor levels.[163] (6) Hyperfibrinolysis due to impaired hepatic clearance of plasminogen activators and/or reduced synthesis of endogenous inhibitors of fibrinolysis (α_2-antiplasmin, TAFI) is also common with advanced liver disease.[158,159]

In spite of all the potential defects in hemostasis that may occur in association with liver disease, results of routine coagulation tests such as the PT/INR and aPTT correlate poorly with clinical bleeding, and these patients may indeed have thrombotic events. An emerging concept to explain this is that the coagulation system is "rebalanced," due to the coexisting alterations of both procoagulant and anticoagulant factors.[147] In support of this notion, plasma from cirrhotic patients has been shown to have comparable thrombin-generating ability as plasma from healthy subjects when measured with assays that reflect the action of both procoagulant and anticoagulant factors.[164,165] Although it may be rebalanced, the coagulation system in patients with chronic liver disease is clearly in a more tenuous state than that of healthy individuals.[147]

Patients with severe decompensated liver disease and markedly abnormal coagulation test results are at increased risk for bleeding, and surgery should be avoided except as a lifesaving measure. In evaluating hemostasis in patients with less severe disease, the PT/INR and aPTT may be good indicators of decreased synthesis of clotting factors and vitamin K deficiency, but they are poor predictors of bleeding risk. Several studies have shown the failure of the PT/INR and aPTT to predict bleeding following liver biopsy.[13,166-170] Similarly, preoperative hemostatic testing has generally not been shown to be clinically useful in predicting bleeding during liver transplantation.[171] A study in patients with liver disease found that INR values in the range of 1.3 to 2.0 generally correspond to levels of factors II, V, and VII that are adequate for hemostasis.[172] A preoperative platelet count is needed to identify thrombocytopenia, and some assessment of platelet function may be useful to determine whether platelet function is abnormal in the setting of a normal or near-normal platelet count. A thrombin time or fibrinogen level should also be performed to evaluate for dysfibrinogenemia. Tests for fibrinogen/fibrin degradation products, D-dimer, euglobulin clot lysis time, or thromboelastography may be useful in evaluating for disseminated intravascular coagulation (DIC) or accelerated fibrinolysis.

In patients with mild liver disease and mild-moderate PT/INR prolongation (<2.0), serious surgical bleeding is unlikely in the absence of other hemostatic abnormalities, and prophylactic intervention is generally not necessary for low- or moderate-risk surgery. For high-risk surgery or greater degrees of hemostatic abnormality, transfusion of fresh frozen plasma is the most commonly used approach for correcting the coagulation abnormality, although there are no good prospective studies to guide the use of fresh frozen plasma in this situation, and there are guidelines that caution against the indiscriminate use of plasma before invasive procedures.[173] It should be noted that the PT of fresh frozen plasma is approximately 15 seconds, so complete correction of the patient's PT/INR cannot usually be achieved.[174] Administration of platelets should be considered for more severe degrees of thrombocytopenia, although recovery will be decreased in the presence of splenomegaly. Administration of DDAVP may be useful in correcting abnormal platelet function in some cases.[175] Administration of 5 to 10 mg vitamin K will usually shorten the PT/INR if vitamin K deficiency is a contributory factor. As discussed earlier, antifibrinolytic agents may also be useful in the reduction of perioperative hemorrhage in patients with liver disease.

INTRAOPERATIVE AND POSTOPERATIVE BLEEDING

Excessive bleeding during or after surgery is a serious and potentially life-threatening complication that requires immediate evaluation and a rapid approach to diagnosis and institution of treatment. The first consideration should be to differentiate between "surgical" and "coagulopathic" causes of bleeding. Failure to surgically control bleeding vessels at the operative site is the most frequent cause of postoperative bleeding and is suggested by evidence of hemorrhage only at the operative site and seen as expanding hematoma, excessive blood in surgical drains, or saturated wound dressings. Conversely, coagulopathic bleeding is suggested by slower "oozing" at the operative site in addition to evidence of bleeding outside the operative field that may be seen as petechiae, purpura, or bleeding at sites of venipuncture, urinary or vascular catheters, or nasogastric and endotracheal tubes.[176] In addition to careful physical examination, laboratory tests, including PT/INR, aPTT, and platelet count, are an essential part of the evaluation. Other useful tests may include a fibrinogen level, a test for fibrin degradation products or D-dimer, euglobulin clot lysis time, or thromboelastography to search for evidence of DIC or fibrinolysis. The peripheral blood smear should also be reviewed to examine platelet morphology and number and to identify possible red blood cell fragmentation that may occur in DIC. The possibility of a preexisting hemostatic abnormality that may have been undetected before surgery should also be considered. Revisiting the patient's family and past medical history, along with a thorough review of preoperative medication use, may yield important diagnostic clues.

When evaluating hemostatic test results in surgical patients, changes that normally occur in response to surgery must be considered. These vary depending on the extent of tissue dissection and duration of the procedure. Consumption as well as hemodilution from crystalloid and blood product infusion both lead to acute reductions of coagulation factors and platelets during surgery and in the initial postoperative period. This is typically followed by changes resulting from the acute phase response, including increases in fibrinogen, platelet count, factor VIII, and plasminogen activator inhibitor I during the first postoperative week.[177]

Alterations in coagulation factor levels that occur during surgery and in the initial postoperative period can limit the reliability of the PT/INR and aPTT in evaluating the bleeding surgical patient. Clinical practice guidelines have consistently recommended transfusion of fresh frozen plasma when PT/INR and aPTT results exceed the mean reference range by 1.5 times.[133,178-183] However, a prospective study of 16 patients with bleeding caused by dilutional coagulopathy following spinal surgery found significant variability in the PT/INR and aPTT and suggested that depending on which test system was used, clinical decisions regarding coagulation factor replacement therapy might differ.[184] Conversely, another and larger retrospective study in a similar patient population found that the PT/INR and aPTT had sufficient sensitivity and specificity to be helpful in guiding transfusion therapy,[185] and some consensus panel guidelines do recommend that transfusion of fresh frozen plasma and cryoprecipitate in the bleeding surgical patient be guided by coagulation studies.[186] Additional prospective studies of patients undergoing other types of surgery are needed to more clearly define the role of coagulation testing in the management of surgical bleeding. In addition, assays that measure thrombin generation or global hemostasis such as thromboelastography may be useful in this setting but await further study and clinical validation.

Coagulopathy Associated With Massive Blood Loss/Transfusion

Massive bleeding (loss of one or more blood volumes in a 24-hour period) may occur in the setting of severe trauma or major surgery and requires aggressive fluid resuscitation and transfusion of blood products. The mechanisms involved in the coagulopathy that accompanies massive transfusion have not yet been fully elucidated but are multifactorial in nature.[187] Similar to chronic liver disease, procoagulant, anticoagulant, profibrinolytic, and antifibrinolytic factors are all affected, resulting in a complex coagulopathy. Impaired thrombin generation is compensated in part by reduction in the activity of antithrombin and other protease inhibitors. Fibrinogen levels can fall rapidly and are proportional to the degree of hemodilution. Antifibrinolytic protein levels are decreased, rendering clots more susceptible to fibrinolysis.[188] In addition to a dilutional coagulopathy, other complications, including consumptive coagulopathy, hypothermia, electrolyte abnormalities (due to citrate intoxication), and acid-base disturbances, may also develop.[188]

In patients without a preexisting coagulopathy, replacement of approximately 1.5 blood volumes is the threshold for the development of dilutional coagulopathy.[189] At that point, PT/INR, aPTT, fibrinogen level, and platelet count should be determined. If the PT/INR or aPTT is prolonged greater than 1.5 times control, the fibrinogen level is below 100 mg/dL, or the platelet count is reduced to 50,000 to 70,000/μL, clinical coagulopathy is suspected and appropriate blood product administration is indicated, particularly if additional blood loss is expected. The same coagulation parameters should be measured again with the replacement of each additional half blood volume (i.e., 5 to 6 units of red blood cells).[190]

Over the last several years, there has been an increased emphasis on more aggressive blood component therapy, driven by data from both military and civilian trauma populations.[191-196] These studies have demonstrated that higher ratios (approaching 1:1) of plasma and platelets to red blood cells are associated with improved outcomes in massively transfused patients. Patients receiving less than massive transfusion may also benefit from higher plasma to red blood cell ratios.[197] Furthermore, maintaining an adequate fibrinogen level is essential for successful management of dilutional coagulopathy.[188]

With prolonged hypotension, acidosis, or extensive tissue trauma and ischemia, tissue factor and tissue plasminogen activator may be released into the bloodstream, initiating DIC. Obstetric catastrophes also commonly result in DIC. Consumptive coagulopathy results in hemostatic failure at lower volumes of blood loss or replacement, and simple administration of blood components may not correct the coagulopathy. In these circumstances, restoration of systemic and hepatic perfusion (the liver is an important site of clearance of fibrin degradation products and activated coagulation factors) is essential for regaining control of hemostasis.

Cardiopulmonary Bypass

Cardiopulmonary bypass is associated with unique hemostatic changes. Perfusion through the extracorporeal membrane oxygenator has profound effects on platelets and clotting factors: platelet count, hematocrit, and levels of coagulation and fibrinolytic factors are reduced to approximately 50% of baseline after starting bypass and remain reduced throughout the procedure, with the exception of factor V, which may be further reduced to less than 20%.[198-201] These changes may be caused in part by exposure to artificial surfaces and also by a tissue factor–dependent pathway related to surgical trauma.[202] Cardiopulmonary bypass results in significant platelet dysfunction[203] reflected by release of α-granule contents, the generation of platelet microparticles, abnormal in vitro platelet aggregation test results, and a prolonged bleeding time that usually corrects within 1 hour postoperatively.[199-204] In addition to quantitative and qualitative defects, cardiopulmonary bypass also results in platelet activation, which may contribute to thrombotic and inflammatory complications.[204] Patients with acute ischemic coronary syndromes (who may be candidates for urgent cardiac surgery) are often given GPIIb/IIIa inhibitors, which may further impair platelet function. If surgery cannot be delayed, consideration of prophylactic platelet transfusions may be required.[205] Inadequate neutralization of heparin with protamine sulfate may result in a prolonged aPTT and thrombin time with a normal reptilase time and is an indication for administration of additional protamine sulfate. The use of DDAVP, antifibrinolytic drugs, and rFVIIa to reduce the hemorrhagic complications of cardiac surgery was discussed earlier. Fibrinogen concentrate has also been shown to reduce blood loss and transfusion requirements during cardiac surgery.[206]

Orthotopic Liver Transplantation

In addition to the complex coagulopathy of end-stage liver disease, orthotopic liver transplantation is accompanied by major alterations in hemostasis. The surgical procedure itself can be divided into three stages, each with its own profile of coagulation abnormalities.[207] Bleeding during the preanhepatic stage, while the host liver is surgically isolated, is due primarily to the patient's preexisting coagulopathy and is determined by the severity of the underlying liver disease. Excessive fibrinolysis may be encountered during this stage in 10% to 20% of those with cirrhosis. The anhepatic stage begins with surgical removal of the liver. Bleeding during this stage is primarily hemostatic because of DIC and excessive fibrinolysis.[208] As the donor liver is reperfused, the postanhepatic stage begins, and serious bleeding is often encountered as a result of a combination of hyperfibrinolysis, metabolic acidosis, hypothermia, electrolyte abnormalities, and sometimes impaired cardiac function.[208,209]

The multifactorial nature of the coagulopathy associated with orthotopic liver transplantation requires a combination of therapeutic interventions. In addition to transfusion of blood products, other hemostatic agents such as DDAVP and antifibrinolytics may be useful and were discussed earlier. There has also been much interest in the use of rFVIIa, and some randomized placebo-controlled trials have been completed. In one study, a single dose of rFVIIa before surgery failed to reduce the number of red blood cell transfusions required.[210] Another study used repeated doses of rFVIIa during surgery, which also failed to reduce the number of red blood cell units transfused or intraoperative blood loss. However, a small but significant increase in the number of patients who avoided red blood cell transfusion entirely was observed in the treatment group.[211] A recent systematic review of these, plus three additional studies, evaluating a total of 215 patients who received prophylactic rFVIIa at the time of liver transplantation, found no effect on mortality or thromboembolism.[118]

Although there may be a trend toward reduced red blood cell transfusion requirements, neither operating room time nor length of stay in the intensive care unit is reduced by the prophylactic use of rFVIIa in this setting.[118] As for other types of surgery, questions about optimal dosing, cost-effectiveness, and safety remain to be fully answered, and it is still questionable whether rFVIIa should be used as prophylaxis in liver transplant patients outside of a prospective clinical trial.[212]

Perioperative Anticoagulation Management

Hematologists are frequently consulted for advice on the perioperative management of patients who are taking oral anticoagulants. Important considerations to be taken into account include (1) the bleeding risk associated with the surgery; (2) the underlying indication for anticoagulant therapy; (3) in the case of secondary antithrombotic prophylaxis, the remoteness of the most recent thrombotic event; (4) other comorbid conditions that may increase the risk for thrombosis and/or the potential consequences of thrombosis while oral anticoagulation is temporarily interrupted; and (5) the half-life of the anticoagulant agent. Regarding the first point, experience has accumulated in recent years suggesting that many relatively minor procedures can be carried out without any interruption of warfarin therapy.[213] These include minor dental procedures (single or multiple extraction, endodontic procedure), cataract removal, minor dermatologic procedures, and low-risk endoscopy procedures. Audits have suggested that discontinuation of anticoagulation is excessively frequent in these situations and discordant with guidelines.[214] Apart from the risk for thromboembolism, the inappropriate use of bridging therapy may also conversely place the patient at risk for bleeding complications, which can set in motion a potentially morbid chain of clinical events. Suggested management strategies are summarized in Table 161-3.

Traditionally, patients on chronic oral anticoagulation with vitamin K antagonists were admitted to hospital several days before surgery for "bridging" anticoagulation, at which time warfarin was discontinued and dose-adjusted unfractionated heparin (UFH) was administered by continuous infusion. The short half-life of UFH allows it to be safely discontinued approximately 4 to 6 hours ahead of the procedure. More recently, there has been a trend toward the use of LMWHs in place of UFH.[215-218] LMWHs have the advantage that in most patients with normal renal function, no monitoring is required, so that therapy can be administered in the outpatient setting. In addition, the risk for heparin-induced thrombocytopenia (HIT) is less with LMWHs.[219] However, the longer half-life (generally in the range of 4 to 6 hours) necessitates withdrawal of these agents at least 12 hours (for prophylactic doses) or 24 hours (for full therapeutic doses) preoperatively, although even then significant circulating anticoagulant activity may remain in the plasma.[220] Bridging with UFH may still be appropriate for some patients, for example, those with an estimated creatinine clearance less than 30 mL/min in whom the half-life of LMWHs may be prolonged, some patients with mechanical prosthetic heart valves (see later), or those at increased risk for bleeding if treated on an outpatient basis. To date there are no published randomized controlled trials data on which to base decisions regarding the relative efficacy and bleeding risks of perioperative anticoagulation management. One concern with the lack of randomized studies is the fact that it has been assumed that heparins are equally efficacious as warfarin in reducing the risk for arterial thromboembolism in patients with atrial fibrillation (AF) or mechanical heart valves, whereas in fact there are few data to support this assumption.[221]

In recent years, oral anticoagulants that directly inhibit thrombin or factor Xa have been licensed for the prevention of stroke and systemic embolism in patients with nonvalvular AF (see Chapter 149). At the time of writing, both dabigatran etexilate (Pradaxa, a direct thrombin inhibitor) at a dose of 150 mg twice daily (75 mg twice daily for patients with a creatinine clearance <30 mL/min),[222-224] and rivaroxaban (Xarelto, a factor Xa inhibitor) at a dose of 20 mg once daily (15 mg for patients with creatinine clearance of 15 to 49 mL/min)[225,226] have been licensed in the United States for these indications. Based on the results of the recently published Apixaban for Reduction in Stroke and Other Thromboembolic Events in Atrial Fibrillation (ARISTOTLE) trial,[227] the licensure of apixaban (Eliquis), another oral factor Xa inhibitor, can also be anticipated. All of these agents have a more rapid onset (within 1 to 3 hours) of action than warfarin,[228] whose peak action occurs after 4 to 5 days. In addition, they share a low potential for drug-food and drug-drug interaction and a predictable response that eliminates the need for routine coagulation monitoring. A consistent finding with these agents is a lower rate of intracranial hemorrhage compared with warfarin.[228-230] Based on the completed or soon-to-be-completed phase III trials in the treatment of venous thromboembolism,[231-233] it can be anticipated that one or more of these agents will also soon receive approval for this indication.

Temporary interruption of oral anticoagulants is often required for more major surgery. Even with a normal diet, 4 to 5 days should be allowed for full or near-full reversal of warfarin when it is being targeted to an INR of 2.0 to 3.0. A more rapid reversal over 24 to 36 hours can be achieved if necessary by administration of a small oral dose of vitamin K_1 (1.0 to 2.5 mg).[234,235] Large doses of vitamin K_1 (>10 mg) are generally unnecessary for this purpose and will lead to prolonged refractoriness to warfarin after it is reinitiated. Although frequently used, subcutaneous administration of vitamin K_1 is associated with highly variable absorption and should be avoided. Intravenous vitamin K_1 has the advantage of more rapid INR reversal compared to the oral route,[236] but it should be administered slowly to avoid anaphylactoid reactions. Urgent reversal of oral anticoagulation before surgery may call for the administration of fresh frozen plasma, although large volumes (15 to 20 mL/kg) are usually required to reverse the INR, and indeed complete normalization cannot usually be achieved. Furthermore, the effect is relatively short-lived

Table 161-3 Perioperative Management Strategies for Patients on Chronic Oral Anticoagulant Therapy

Clinical Situation	Suggested Anticoagulation Management
Low-bleeding-risk surgery (dental, cataract, skin)	Reduce dose of OAT to achieve INR ≤2.0
Low thrombotic risk Aortic valve prosthesis without other thrombotic risk factors* or AF with low stroke risk or VTE > 3 months previously	Stop OAT 4 nights before surgery Safe to operate when INR ≤1.5 Restart OAT on evening of surgery Use prophylactic perioperative UFH/LMWH if indicated (depends on type of surgery)
Moderate thrombotic risk Mitral or multiple prostheses or Aortic prosthesis with risk factors for thrombosis or AF at high stroke risk or VTE within past 3 months	Stop OAT 4 days before surgery Begin IV UFH† when INR < 2.0 (target aPTT = 2-3 × control) Stop heparin 5 hours before surgery Begin UFH prophylaxis and OAT as soon as possible postoperatively; continue heparin until INR has been therapeutic for >48 hours

Modified from Dorman BH, Spinale FG, Bailey MK, et al: Identification of patients at risk for excessive blood loss during coronary artery bypass surgery: Thromboelastography versus coagulation screen. *Anesth Analg* 76:694, 1993.
AF, Atrial fibrillation; *INR,* international normalized ratio; *LMWH,* low-molecular-weight heparin; *OAT,* oral anticoagulant therapy; *UFH,* unfractionated heparin; *VTE,* venous thromboembolism.
*Risk factors include caged-ball or single tilting-disk valve, AF, history of stroke/transient ischemic attack/other embolic event, left ventricular failure, underlying hypercoagulable state, including cancer.
†LMWH at full-treatment doses may also be used for bridging, although a Food and Drug Administration warning about their use in patients with mechanical valve prostheses was issued in 2002 (discussed in text).

because of the short half-life (approximately 6 hours) of transfused factor VII. Therefore concomitant vitamin K_1 administration is required to ensure maintenance of adequate hemostasis. Prothrombin complex concentrates (PCCs; 25 to 50 units/kg) may be used to control hemorrhage in warfarin-treated patients with active bleeding,[235,237-239] and they have been used to expeditiously reverse warfarin therapy before emergency surgery.[169] These concentrates are manufactured by fractionation of pooled plasma and contain the vitamin K–dependent factors II, VII, IX, and X. However, it is important to be aware that there is significant heterogeneity among these agents, with some (three-factor PCCs[238]) having a low concentration of factor VII, which may leave the INR prolonged following administration.[240] At the time of writing, practice in the United States is at variance with most other developed nations in the lack of an available four-factor PCC, although licensure of at least one product for warfarin reversal is anticipated in the near future. PCCs also vary in their content of heparin and antithrombin, and the vitamin K–dependent anticoagulant proteins C and/or S.[238,241] They are all subjected to one or more virucidal processes. Concern has been raised that PCCs may be associated with an increased risk for thrombosis. However, the reports of thrombosis with these agents generally preceded the availability of modern-day nonactivated concentrates and occurred in patients with hemophilia who had received greater than 200 units/kg/day for several days. Nonetheless, because the thrombotic risk might be accentuated in the perioperative period, the risks and benefits of these agents to reverse anticoagulation before surgery need to be carefully weighed. The use of rFVIIa to reverse anticoagulation before emergency surgery has also been reported,[242] but further experience has shown that although rFVIIa will correct the INR, this may not equate to hemostatic efficacy in vivo.[243]

Thus far, there has been scarce published experience on outcomes following reversal of oral direct thrombin and Xa inhibitors before elective or emergency surgery.[244] A working knowledge of the respective elimination half-lives of these agents is important in deciding when to discontinue before elective procedures. In addition, an appreciation of the dominant mechanism(s) of clearance that may affect the elimination half-life is essential (Table 161-4). In general, when the procedure is considered to be more than minor, and the aim is to have negligible amounts of drug (<10%) in the circulation at the time of surgery, the drug should be discontinued at a time before surgery equivalent to four to five half-lives. This would imply 2 to 3 days (48 to 60 hours) for dabigatran.[222,223,228,245-247] Patients undergoing minor surgery could omit the drug for 1 day, expecting that there will still be some residual anticoagulant effect at the time of surgery. These recommendations may need to be amended for patients with reduced renal function or in those over the age of 75. Given the shorter half-life of rivaroxaban, omission of the drug on the day before surgery should be sufficient to ensure normal hemostasis.[225,244,246] Notably, in the event of emergency surgery or life-threatening bleeding, none of the new oral anticoagulants has a specific antidote and there remains significant uncertainty about the optimal urgent reversal strategy. Both PCCs and rFVIIa have been suggested, but as yet there is very limited clinical experience with either.[244,246]

Table 161-4 Suggested Timing of Interruption of Oral Xa or Thrombin Inhibitor Before Surgery

Calculated Creatinine Clearance (mL/Min)	Half-Life (Hr)	Standard Risk for Bleeding (e.g., Colonoscopy, Cholecystectomy)	High Risk for Bleeding (e.g., Neurosurgery, Cardiac Surgery)
DABIGATRAN			
>80	13 (11-22)	24 hr	2 days
>50-<80	15 (12-34)	24 hr	2 days
>30-<50	18 (13-23)	2 days	4 days
<30	27 (22-35)	4 days	6 days
RIVAROXABAN			
>30	12 (11-23)	24 hr	2 days
<30	Unknown	2 days	4 days

Modified from Schulman S, Crowther MA: How I treat with anticoagulants in 2012: New and old anticoagulants, and when and how to switch. *Blood* 119:3016, 2012.

Depending on the estimated risk for thrombosis when long-term oral anticoagulation is temporarily discontinued, bridging with LMWH (or UFH) may be required while the INR is in the subtherapeutic range.[213,218,248,249] In this regard, a number of specific issues, which are considered in the next several paragraphs, surround each of the three most common indications for long-term oral anticoagulation therapy, namely VTE, AF, and mechanical cardiac valve prostheses.[250] Although no LMWH yet has FDA approval for this purpose, large case series support the safety of this approach.[249,251-253] Regardless of whether bridging anticoagulation with UFH or LMWH is employed, the INR should be checked preoperatively to ensure that the pharmacologic effect of warfarin has been adequately reversed. As a rule, most surgeries can be safely carried out when the INR is less than 1.5.

Venous Thromboembolism

Patients are generally anticoagulated with warfarin to a target INR of 2.0 to 3.0 for several months to years after an acute episode of VTE (here defined as deep venous thrombosis [DVT] with or without pulmonary embolism [PE]) (see Chapter 151). Before deciding on a perioperative anticoagulation management strategy in these patients, it is helpful to assess separately the risks for bleeding and recurrent VTE in the preoperative and postoperative periods.[215] Although somewhat dependent on the type and magnitude of the intervention and method and duration of anesthesia, the risk for thrombosis may be magnified up to 100-fold during the postoperative period.[254] In some individuals, for example, those with a critically reduced cardiopulmonary reserve, even a minimal risk for PE may be unacceptable. Conversely, the potential consequences of even a modest amount of bleeding may be unacceptable in certain situations, for example, bleeding into an enclosed space such as the central nervous system in a patient undergoing neurosurgery.

It has been estimated that the risk for a recurrent event after an acute VTE without anticoagulant therapy is approximately 40% at 1 month.[215] Even in patients appropriately treated with anticoagulants, the cumulative risk for recurrent VTE at 3 months is on the order of 6% to 8%, with approximately three-quarters of events occurring within the first 3 to 4 weeks.[254-256] The risk gradually recedes thereafter, such that it is essentially back to baseline by approximately 3 months. However, the baseline risk may itself vary considerably. For example, in the case of an individual with a history of idiopathic VTE (i.e., not associated with surgery, pregnancy/oral contraceptive therapy, or trauma), it may be as high as 10% to 15% per year, at least during the first 2 to 3 years.[257,258] Especially high rates of recurrence may also be seen with underlying cancer, chronic cardiorespiratory disease, or antiphospholipid syndrome.[258] Therefore wherever possible it is usually preferable to delay elective surgery for at least 2 to 3 months after an acute episode of VTE. In the extreme situation where surgery is unavoidable within the first month after an acute VTE, the risk-benefit ratio usually favors bridging with full-dose UFH or LMWH before surgery and resuming again as soon as possible after surgery.[213, 215,218] When the bleeding risk precludes the use of anticoagulation, the use of an inferior vena cava (IVC) filter may need to be considered. Generally speaking, a delay of 12 hours is sufficient to ensure adequate hemostasis after surgery before prophylactic doses of heparin are reinitiated, although of course this will also depend on the type of surgery and its customary bleeding risks. However, when therapeutic-dose anticoagulation is indicated, the ninth edition of the American College of Chest Physicians (ACCP) guidelines

recommend that resumption be delayed until 48 to 72 hours following surgery.[239] When UFH is used, no bolus dose should be administered to avoid overanticoagulation and the attendant increased risk for bleeding. In the second or third month after an acute VTE, the heightened risk for VTE after surgery still favors full-intensity heparin therapy initiated as soon as possible in the postoperative period. However, the preoperative risk for recurrence has receded to the point where prophylactic doses of subcutaneous heparin or LMWH are probably sufficient.[215] One of these agents should be initiated when the INR is less than 2.0 and continued until approximately 12 hours preoperatively. In most patients who are 3 or more months remote from their most recent episode of VTE, preoperative bridging anticoagulation is usually unnecessary. Standard postoperative prophylaxis with LMWH/UFH is then administered with simultaneous reinitiation of warfarin.

Atrial Fibrillation

Several large prospective studies have established the major risk factors for and rates of embolic stroke and bleeding for patients with nonvalvular AF.[259-261] The $CHADS_2$ score[261] (Congestive heart failure, Hypertension, Age >75 years, and Diabetes mellitus, and 2 points for prior Stroke/transient ischemic attack) is the most widely used risk stratification model to define the risk for embolization in nonvalvular AF. Thus low-thrombotic-risk patients include those who are younger (<75 years) with "lone" AF and no additional risk factors for stroke, such as a previous history of stroke or transient ischemic attack, hypertension, diabetes, or left ventricular dysfunction. Their risk for stroke without anticoagulant therapy (and while not in the postoperative period) is estimated to be less than 1% per year, although there are limited clinical trials data on this topic.[262] At the opposite end of the spectrum, the estimated risk for stroke may approach 15% per year in older adult patients (>75 years) with a previous history of stroke and one or more of the risk factors listed.

Depending on the procedure, a reasonable approach to perioperative anticoagulation management in patients with AF is to discontinue oral anticoagulation 4 to 5 days ahead of a planned major surgery, with no bridging therapy except for those at high risk (stroke or transient ischemic attack within previous month, rheumatic mitral valvular disease, nonvalvular AF with two or more risk factors). A large single-center series, using a standardized algorithm of full-treatment-dose LMWH bridging in patients at risk for arterial thromboembolism (mechanical heart valve, AF, or thromboembolic stroke), reported a thromboembolism rate of 0.4%, and a 0.7% incidence of major bleeding.[263] Other studies and registries have reported rates of major bleeding as high as 8%.[249] In the case of the oral thrombin and Xa inhibitors, a time frame for discontinuation dependent on the respective elimination half-life has already been discussed. However, of some concern in the clinical trials was the increased risk for stroke in AF patients discontinuing rivaroxaban,[264] which led to a black box warning from the FDA that another agent be considered for bridging if the drug is discontinued for a reason other than bleeding.

Mechanical Prosthetic Heart Valves

The major thrombotic risks associated with mechanical prosthetic heart valves are systemic embolization and valve thrombosis, which usually presents as acute congestive heart failure. These risks are dependent on the location of the valve (higher in the mitral position than the aortic position), number of valves, and type of valve.[265] The earlier model ball-and-cage valves (e.g., Starr-Edwards) are considered to be more thrombogenic than the single-leaflet tilting-disk models (e.g., Björk-Shiley, Medtronic-Hall), which in turn are more thrombogenic than the bileaflet tilting-disk models (e.g., St. Jude Medical). The annual risk for thrombosis in patients with mechanical valves not receiving oral anticoagulation will therefore vary with (1) the type and location of the valve(s) and (2) certain comorbidities that increase the thrombotic risk, such as AF, congestive heart failure, enlarged left atrium, left ventricular aneurysm, and intracardiac thrombus. Estimates of the risk for thrombosis without anticoagulation are generally in the range of 8% to 15% per year, but these figures may be exaggerated owing to the overrepresentation of older-model valves in these series.[265]

It is generally agreed that bridging with UFH or LMWH is unnecessary for the patient with an isolated prosthetic valve in the aortic position without any other major risk factors who is to undergo elective surgery. Warfarin therapy is discontinued 4 to 5 days ahead of the procedure and is reinitiated as soon as possible after surgery along with prophylactic doses of UFH or LMWH.[252,266-268] On the other hand, bridging may be indicated for patients with an aortic valve prosthesis and other risk factors for thrombosis, for mitral valve prosthesis, and for multiple valvular prostheses. A growing experience with outpatient LMWH bridging (given at full therapeutic doses) suggests that it may be as effective and safe as UFH, at a lower overall cost.[249] However, in 2002, the manufacturers of enoxaparin issued a drug label warning indicating that the use of enoxaparin was not recommended for thromboprophylaxis for patients with prosthetic heart valves.[269] This action was prompted by the deaths of two pregnant patients with prosthetic valves from thrombotic complications while taking enoxaparin. The warning was subsequently reworded to acknowledge that the standard approach—infusional dose-adjusted UFH—has also been associated with adverse thrombotic outcomes in pregnant women with prosthetic heart valves, and that this topic has not been studied adequately.[267,270,271] It is therefore likely that pregnancy represents a very different situation with respect to the failure rate of all heparins in bridging. The accompanying hypercoagulable state and increased plasma volume and glomerular filtration rate (which can affect the volume of distribution of the drug) contribute to the uniqueness of the pregnant patient with a prosthetic valve.[272,273] In the absence of data from randomized controlled trials, consensus is moving toward recommending the use of LMWH without routine monitoring for bridging anticoagulation in nonpregnant patients, based on an absence of evidence of any lesser efficacy or safety.[213,218,266] LMWH is probably also a reasonable option for longer-term prophylaxis in the pregnant patient who cannot take warfarin, although in this situation routine periodic monitoring of anti-Xa activity is recommended with appropriate dose adjustments to target a peak anti-Xa activity (4 to 6 hours after dosing) of 0.7 to 1.2 units/mL.[267,271] The relatively low enrollment of subjects with mechanical heart valves receiving LMWH in registries of bridging anticoagulation suggests that there remains some reluctance to use this approach.[249,274] Indeed, recommendations from the American College of Cardiology and American Heart Association continue to recommend UFH given by continuous infusion rather than LMWHs for bridging in patients at high risk for thrombosis.[267] This category would include all patients with mitral or tricuspid valve replacements and those with an aortic valve replacement and additional risk factors (AF, previous thromboembolism, a "hypercoagulable condition," older-generation mechanical valves, more than one mechanical valve, or a left ventricular ejection fraction <0.3). It is clear that there is clinical equipoise in the optimal choice of bridging for higher-risk patients, and data from prospective randomized clinical trials are urgently required to resolve the issue.

Management of Anticoagulation in Patients Undergoing Dental Surgery

A common reason for hematologic consultation is to provide recommendations for the patient on long-term oral anticoagulation therapy for whom dental surgery, including dental extraction(s), is scheduled. In a randomized clinical trial, a nonsignificant increase in bleeding complications occurred in patients continued on oral anticoagulation without adjustment (other than ensuring that the INR was <4.0), compared to an intervention group in which anticoagulation was discontinued for 2 days to achieve an INR less than 2.0.[275] Similar results were reported from a large prospective case-control study in Italy, where no difference in bleeding complications after dental

extraction was observed in patients taking oral anticoagulant therapy (with INRs in the range of 1.8 to 4.0) compared to controls.[276] In this study, local hemostatic measures (fibrin sponges, silk sutures, and tranexamic-soaked gauzes) were used in anticoagulated patients. It is likely also that the concurrent use of an antifibrinolytic agent mouthwash—which has independently been shown to reduce blood loss in this situation[277,278]—would further diminish the bleeding risk.

Management of Anticoagulation in Patients Undergoing Gastrointestinal Endoscopic Procedures

When a clinician is deciding on the most appropriate periprocedural management of oral anticoagulant therapy in patients undergoing gastrointestinal endoscopy, a working knowledge of the bleeding risk associated with the various interventional procedures is required (Table 161-5). Although simple diagnostic colonoscopy is associated with a very low bleeding risk (approximately 0.1%), colonic polyps will be identified in approximately one-third of patients undergoing routine screening. Endoscopic polypectomy may be associated with a significant (1% to 5%) bleeding risk.[279] Risk factors for hemorrhage include hypertension, polyp size, sessile morphology, and location in the ascending colon. Bleeding in patients on anticoagulation is frequently delayed, with a median onset at approximately 5 days, although it may be encountered up to 14 days after the procedure.[280] Current guidelines are based on smaller trials and expert opinion. The guidelines of the American Society for Gastrointestinal Endoscopy[281] and the European Society of Gastrointestinal Endoscopy[282] recommend continuing warfarin in the therapeutic range in patients who have a low risk for bleeding (e.g., upper- or lower-gastrointestinal endoscopy with or without biopsy). On the other hand, interruption of anticoagulation (either temporary cessation or halving the dose for several days preoperatively in all but the highest-thrombotic-risk patients[283]) is recommended in those undergoing high-risk procedures (see Table 161-5). In those patients with the highest risk for thromboembolism (e.g., AF with valvular disease and/or prior history of stroke), bridging anticoagulation with heparin is recommended before and after high-risk procedures.[284]

Similarly, the decision whether to temporarily interrupt antiplatelet agents should be made after weighing the risks for thrombosis if withheld and bleeding if continued (which will depend to some extent on the type of procedure). Current guidelines[281,282] recommend continuation of aspirin irrespective of polyp size, but discontinuation of thienopyridines (5 days for clopidogrel, 7 days for prasugrel) for polyps greater than 1 cm in patients in whom the risk for thrombosis is not judged to be excessive. For patients who cannot discontinue these agents, the judicious use of topical hemostatic devices should be considered.

Table 161-5 Risk for Bleeding Associated With Various Endoscopic Procedures

Low-Risk Procedures	High-Risk Procedures (Approximate Bleeding Risk [%])
Diagnostic esophagogastroduodenoscopy	Colonoscopic polypectomy (1%-2.5%)
Flexible sigmoidoscopy and colonoscopy ± biopsy	Gastric polypectomy (4%)
Diagnostic endoscopic retrograde cholangiopancreatography	Laser ablation and coagulation (<6%)
Biliary stent insertion without endoscopic sphincterotomy	Endoscopic sphincterotomy (2.5%-5%)
Endosonography	Dilation of benign or malignant strictures
Push enteroscopy	Percutaneous endoscopic gastrostomy

Management of Anticoagulation in Patients Receiving Neuraxial Anesthesia

A special situation concerns the management of perioperative anticoagulation, particularly LMWHs, in patients receiving neuraxial (spinal and epidural) anesthesia or analgesia for surgery or delivery. The advantages of these forms of regional anesthesia compared to systemic anesthesia (superior analgesia, decreased transfusion requirements, and lower incidence of thrombotic complications) must be weighed against the risk for spinal hematoma. This rare but potentially disastrous complication is a result of needle- or catheter-induced vascular trauma during placement into the subarachnoid or epidural space. Bleeding usually occurs into the epidural space, probably because of the prominent epidural venous plexus.[285] It presents more frequently as a delayed but progressive sensory or motor deficit, or bladder or bowel dysfunction, rather than radicular back pain. Attention was drawn to this problem in the mid-1990s when multiple cases of spinal hematoma associated with the use of the LMWH enoxaparin were reported to the FDA. Significant risk factors that have been identified include the timing of both needle or catheter placement and removal in relation to the last dose of LMWH, the concurrent use of antiplatelet agents, and trauma during the regional anesthetic procedure.[286] Spinal hematomas have been reported with both single-dose and continuous neuraxial anesthesia, although the risk is considered to be much lower with the former procedure. Recommendations designed to minimize the risk for spinal hematoma include the following: (1) placement of the needle should occur at least 10 to 12 hours after the last prophylactic dose, or longer (e.g., 20 to 24 hours) after the last full therapeutic dose of LMWH, and (2) similarly, removal of an indwelling catheter should be delayed for at least 10 to 12 hours after a dose of LMWH, most of which have a half-life in the range of 4 to 6 hours.[286,287] Once-daily prophylactic LMWH regimens are associated with lower trough anticoagulant levels than twice-daily regimens, and they may be a safer choice in patients in whom indwelling catheters are employed,[288] with removal of the catheter scheduled for 20 or more hours after the last dose of drug. It is generally considered safe to administer the next dose of LMWH 2 hours after catheter removal. The synthetic pentasaccharide fondaparinux (Arixtra) also carries a black box warning from the FDA, although in fact very little is known about the associated risk for spinal hematoma formation. The long plasma half-life of the agent (17 hours) should be borne in mind when making treatment decisions about its use when regional anesthesia is being concurrently employed.[286] As a rule, fondaparinux should be discontinued 36 hours before catheter insertion and not restarted before 6 to 8 hours following the procedure. Avoidance of the simultaneous use of antiplatelet agents, including aspirin and NSAIDs, is advisable in the case of all of these anticoagulants, even though the use of aspirin or NSAIDs in isolation likely does not lead to any increased risk for procedure-related bleeding. It is, however, recommended that thienopyridines be discontinued at an appropriate interval before catheter insertion (e.g., 5 to 7 days in the case of clopidogrel). For further information about this topic, the reader is referred to one of the North American or European guidelines.[286-289]

In the case of the new anticoagulants, there are minimal data on which to base recommendations. However, expert recommendations on the timing of administration of dabigatran and rivaroxaban, based on their pharmacologic profiles, have been published.[290,291]

Prophylaxis for Venous Thromboembolism After Surgery and Trauma

Epidemiology and Natural History

The overall incidence rate of VTE in the community is approximately 1 in 1000 per year. It has been estimated that hospitalization for surgery accounts for about one-quarter of cases of VTE and is

associated with an almost 22-fold increased risk. Trauma accounts for about half as many additional cases, with a 13-fold increased risk.[254] Additional identified risk factors (which may coexist in these individuals) include malignancy, central vein catheterization, and neurologic disease with extremity paresis. Older age is also a strong independent risk factor, whereas hormonal therapies (oral contraceptives, hormone replacement therapy, tamoxifen, and raloxifene) compound the risk in women.[255] In hospitalized patients, DVT is often clinically silent, and PE may be rapidly fatal. It has been estimated that more than 12 million hospitalized patients per year are at risk for VTE.[292] Because screening for asymptomatic DVT by ultrasonography is expensive yet relatively insensitive,[293] widespread use of prophylaxis is widely acknowledged to be the most effective strategy to minimize the burden of venous thromboembolic disease. This strategy has also been shown to be a cost-effective approach.

Although patients on the surgical and trauma services represent a significant proportion of VTE disease burden, they also provide an important opportunity for prevention through the appropriate design and use of validated VTE prophylaxis regimens. A comprehensive treatise with updated recommendations was recently published in the ninth edition of the ACCP guidelines.[294] The reader is referred to these guidelines for details of recommended regimens, frequency, and duration of therapy graded according to level of evidence. Some general principles from this document will be discussed here, with a focus on more recent developments and recent controversies in the field.

Using sensitive techniques such as ascending venography, much has been learned about the frequency and natural history of DVT formation after surgical procedures. In many studies, venography was performed at 7 to 14 days postoperatively, to coincide with the termination of pharmacologic prophylaxis. Recently, however, it has become clear that DVT formation may continue for several weeks after surgery, and the trend in the last several years in certain situations, such as after hip replacement or abdominal/pelvic cancer surgery, has been toward longer duration of therapy, up to 28 to 35 days (discussed further later). These studies have defined the absolute risks for VTE according to these end points and allowed a given individual's risk for VTE to be assessed preoperatively (Table 161-6). Low-risk individuals are defined as those less than 40 years of age undergoing minor surgery lasting less than 30 minutes, with no additional risk factors. At the other end of the spectrum, very high-risk individuals are those more than 40 years of age undergoing major orthopedic lower extremity or spinal surgery, or who have suffered major trauma. A history of prior VTE, use of estrogen-containing therapies, and presence of certain thrombophilic disorders or cancer may further heighten the risk in this group.[295]

Nonpharmacologic Methods of Venous Thrombosis Prophylaxis

Early ambulation should be a routine component of postoperative care whenever possible. It has been shown to be associated with a lower risk for postoperative VTE, for example, after hip replacement surgery.[296] Properly fitted elastic stockings (i.e., those not leading to venous compression above the knee) are a useful adjunct in VTE prophylaxis but are generally insufficient as the sole prophylactic modality. On the other hand, intermittent pneumatic compression devices, both those that provide intermittent calf and/or thigh compression or foot pumping action, may be used as the primary modality in all but the highest-risk group of patients undergoing high-risk general surgery, or hip or knee surgery, and some forms of neurosurgery. These devices presumably reduce the risk for VTE by preventing venostasis in the immobilized limb(s). Although it has been postulated that they also enhance fibrinolysis by stimulating endothelial release of plasminogen activators, it has been difficult to support this hypothesis with experimental data.[297,298] Compliance is a constant concern with these devices, as is the possibility of reduced efficacy in significantly overweight individuals. Intermittent pneumatic compression is often used as an adjunct to pharmacologic prophylaxis in high-risk individuals.[299]

IVC filters are occasionally used to prevent pulmonary embolization in patients with extensive trauma in whom the bleeding risks are (sometimes incorrectly) perceived to be too high for the use of pharmacologic prophylaxis.[300-302] There are very few prospective randomized trials to support the use of IVC filters in this or any other surgical situations, and in one of the few such trials, filter placement was associated with a significantly greater risk for late-onset DVT.[303] Filter deployment may still be a reasonable approach in a patient with a very recent VTE who requires urgent surgery in whom aggressive anticoagulant prophylaxis is not considered feasible. Temporary (retrievable) IVC filters, which generally require removal within 2 to 3 months, are being increasingly used in this type of situation, despite an absence of data from randomized clinical trials.[300] An all-too-frequent issue with these filters is that they are not removed once the indication for their placement has resolved.[304] Furthermore, as the experience with retrievable IVC filters has matured, it has become

Table 161-6 Recommendations for Prophylaxis of Deep Vein Thrombosis

Approximate Risk Category*	Patients	Calf DVT	DVT	PE	Recommendation
Low	Surgical patients under 40, surgery lasting <30 minutes, no additional risk factors	1%-2%	0.5%-1%	0%-0.1%	Ambulation, leg exercises
Moderate	Surgical patients older than 40, having abdominal or thoracic surgery lasting >30 minutes	20%-30%	2%-10%	1%-3%	Low-dose heparin
	Neurosurgery or other patients with high bleeding risk				Pneumatic compression
High	Hip fracture	40%-80%	20%-40%	5%-10%	Warfarin,† LMWH
	Hip replacement				Warfarin,† adjusted-dose heparin, LMWH
	Knee replacement				LMWH, external pneumatic compression
	Open prostatectomy				Pneumatic compression
	Gynecologic malignancy				Pneumatic compression

DVT, Deep venous thrombosis; *LMWH,* low-molecular-weight heparin; *PE,* pulmonary embolism.
*Without prophylaxis.
†Given in low-dose regimen.

clear that long-term complications (including filter limb fracture and/or migration, distal DVT, and IVC thrombosis and/or stenosis) with nonretrieved filters are a serious concern.[305]

Pharmacologic Methods of Prophylaxis

The surgical situations in which there exist the largest body of accumulated clinical trials data are in major orthopedic surgery (total hip and knee arthroplasty, hip fracture, and spinal surgery). As mentioned, the primary end point for VTE in these antithrombotic agent trials has been DVT detected by venography, which occurs in 40% to 70% of patients not receiving prophylaxis.[306] Until the recent publication of the ninth edition of the ACCP guidelines, this surrogate end point for clinically apparent symptomatic DVT was the basis of recommendations for antithrombotic prophylaxis because of its sensitivity and reproducibility. However, the most recent iteration of the guidelines saw a marked shift toward patient-relevant outcomes, even if these outcomes needed to be estimated/extrapolated from the existing evidence. In addition, an emphasis on patient values and preferences was introduced to the panels' deliberations.[307]

Prophylactic UFH is administered subcutaneously, either 5000 units two to three times daily without monitoring or every 8 hours with dose adjustment to maintain a high-normal midinterval aPTT, LMWH (enoxaparin, tinzaparin, or dalteparin) is given subcutaneously once or twice daily (depending on the agent), and warfarin is given postoperatively and adjusted to a target INR of 2.0 to 3.0. Fondaparinux, a synthetic pentasaccharide that selectively inhibits factor Xa in an antithrombin-dependent manner, is also licensed for VTE prophylaxis in total hip and knee arthroplasty surgery and hip fracture surgery.[308] An advantage of LMWHs and other structurally unrelated molecules over UFH is a reduced or absent risk for HIT. For example, clinically apparent HIT was present in 2.7% of patients receiving prophylactic doses of UFH after hip surgery, compared with 0% in the cohort who received LMWH ($P = .0018$).[309] However, HIT may occur as a rare complication of LMWHs such as enoxaparin, tinzaparin, or dalteparin.[219] On the other hand, although HIT has been very rarely described as a result of fondaparinux therapy,[310] accumulating data from case series suggest that fondaparinux can paradoxically be used for the treatment of HIT.[311,312]

In general, all these forms of thromboprophylaxis are associated with roughly a 70% risk reduction in perioperative VTE, but there are some important differences in efficacy that have been demonstrated in specific types of surgery,[295] which are briefly outlined later. Conversely, the bleeding risks are principally related to dose and host risk factors, and to a lesser extent the choice of agent and timing of administration in relation to surgery. For example, in orthopedic surgery in the United States, LMWH is traditionally initiated 12 hours postoperatively, compared to European regimens in which these agents are initiated in close proximity to surgery (between 2 hours preoperatively and 6 to 8 hours postoperatively).[313] Details of suggested dosing schedules are shown in Table 161-7.

Table 161-7 Suggested Dosing Regimens for Prophylactic Low-Molecular-Weight Heparins and Pentasaccharide for Orthopedic or General Surgery

Drug	Orthopedic Surgery	General Surgery
Enoxaparin	30 mg (3000 International Units) every 12 hr Begin 12-24 hr after surgery Continue for 7-10 days Consider extended prophylaxis After THA (40 mg once daily until 28-35 days after surgery)	40 mg (4000 International Units) once daily Begin 1-2 hr before surgery
Dalteparin	5000 International Units once daily	2500 International Units once daily Begin 1-2 hr before surgery
Tinzaparin	75 International Units/kg once daily Begin 1-2 hr preoperatively	
Fondaparinux	2.5 mg once daily Begin 6 hr after surgery	

THA, Total hip arthroplasty.

Orthopedic Surgery

Among the various types of surgery, the efficacy and safety of pharmacologic VTE prophylaxis has been most extensively studied in major orthopedic surgery. However, as discussed later, it has also recently become a highly controversial topic. As mentioned, the primary (surrogate) end point of venographically detected DVT is in the range of 40% to 70% in patients not receiving prophylaxis. The corresponding rates of death due to PE are 0.1% to 0.4% of patients undergoing total hip replacement, 0.2% to 0.7% undergoing total knee replacement, and 3.6% to 12.9% following hip fracture surgery.

In 2007 the American Academy of Orthopaedic Surgeons (AAOS) published their own guidelines for the prevention of perioperative symptomatic PE (www.aaos.org/guidelines). These guidelines differ from those of the eighth edition of the ACCP document by recommending that (1) mechanical prophylaxis be used in all patients; (2) warfarin is a suitable alternative in most patients; and (3) in patients with an increased risk for bleeding, warfarin, aspirin, or mechanical prophylaxis alone is a suitable alternative. A major impetus for the AAOS guidelines was the concern among orthopedic surgeons about bleeding risks associated with antithrombotic agents. Indeed, it has been noted that the lack of standardization of the definition of "major bleeding" in pharmacoprophylaxis clinical trials may result in seriously flawed conclusions about bleeding rates when comparing treatment groups.[314] Although vigorously refuted at first,[315] the principles of the AAOS recommendations—in particular, that only the clinically relevant end points of symptomatic VTE and serious bleeding should be considered when recommending thromboprophylaxis strategies—have been incorporated into the ninth edition of the ACCP guidelines.[307] One acknowledged practical difficulty is determining the relative importance ascribed to these opposing events. As a result of the revised grading criteria, the quality of evidence for many recommendations was downgraded in the ninth edition. One novel recommendation was the inclusion of aspirin as an acceptable method of pharmacoprophylaxis for total hip or knee arthroplasty. In fact, it was assigned a grade 1B recommendation on the basis of the very large Pulmonary Embolization Prevention trial.[316] In this study, 160 mg a day of aspirin initiated preoperatively as an adjunctive therapy to conventional prophylaxis was associated with a reduction in symptomatic PE from 1.2% with placebo to 0.7% ($P < .001$), although there was an increased rate of bleeding requiring transfusion.[317] In contrast, intermittent pneumatic compression (applied for at least 18 hours daily) as the sole method of prophylaxis received a grade 1C recommendation.[316]

Metaanalysis has demonstrated that the protection against proximal DVT afforded by low-dose UFH may be inferior to LMWH, and LMWH is recommended over UFH.[316] An acceptable alternative to LMWH is warfarin, which is preferred by many orthopedic surgeons. Most commonly, warfarin is initiated the evening of surgery, although in some protocols it is begun on the evening before surgery, without any apparent difference in efficacy. Dose adjustment is performed to achieve a target INR of 2.5 ± 0.5. The efficacy of LMWH is either equivalent or slightly superior to warfarin in total hip arthroplasty and more definitively superior in total knee arthroplasty, albeit at the expense of a mildly increased risk for bleeding.[295]

Fondaparinux (2.5 mg once daily) was compared with enoxaparin (40 mg once daily or 30 mg twice daily) in hip and knee arthroplasty and in hip fracture repair.[318-320] In a metaanalysis of the major trials,

which included 7344 patients, there was a statistically significant 55% relative risk reduction (6.8% versus 13.7%) in the incidence of venographically detected DVT (and proximal DVT).[308] However, there was no difference in the incidence of symptomatic VTE or fatal PE, and major bleeding was more frequently encountered in the fondaparinux group compared to the enoxaparin group (2.7% versus 1.7%). It is likely that the higher efficacy at the expense of greater bleeding with fondaparinux is explained by the fact that the first dose was usually administered earlier than enoxaparin (6 hours versus 12 hours postoperatively). Prolonged prophylaxis beyond the usual 7 to 10 days is a pertinent consideration for total hip arthroplasty patients, where the median time to diagnosis of symptomatic VTE (occurring in 2.8% of patients within 3 months) is 17 days postoperatively. In contrast, VTE after total knee arthroplasty (occurring in 2.1% of patients within 3 months) tends to occur much earlier, after a median of 7 days.[306] By metaanalysis, trials in which LMWH prophylaxis was extended for 30 to 42 days were associated with a significant reduction in the frequency of symptomatic VTE, without any increase in major bleeding.[313,321] This was especially true in total hip arthroplasty, where the absolute risk reduction in symptomatic VTE was approximately 2%.[321] Prolonged therapy with warfarin may be similarly effective, although some studies,[322] but not others,[323] have raised concerns about the bleeding risks. As yet, despite early indications of favorable cost-effectiveness, long-term prophylaxis with LMWH or warfarin is not widely used.

The new oral anticoagulants (dabigatran, rivaroxaban, and apixaban) have all been tested against the common comparator, enoxaparin, in phase III clinical trials of VTE prophylaxis in hip or knee replacement surgery.[324-330] A pooled analysis of these studies, which included more than 32,000 randomized patients undergoing total hip or knee arthroplasty, concluded that the new anticoagulants demonstrated significantly better efficacy (considering the end points of total VTE and all-cause mortality, major VTE, and proximal DVT) with an equivalent safety profile (i.e., bleeding).[331] Rivaroxaban (10 mg once daily) has received approval in the United States and elsewhere for the prevention of VTE in patients undergoing elective total hip or knee replacement surgery. Apixaban (2.5 mg twice daily) has also been approved for these indications, as has dabigatran (220 mg once daily) in the European Union and in Canada.[228] In the ninth edition of the ACCP guidelines, LMWH, fondaparinux, apixaban, dabigatran, rivaroxaban, low-dose UFH, or adjusted-dose vitamin K antagonists all received a grade 1B recommendation when used for VTE prophylaxis in these situations.

Recently it has been demonstrated that patients with comparatively minor forms of lower-extremity orthopedic surgery, such as therapeutic arthroscopic knee procedures, are also at increased risk for VTE.[332,333] A recent metaanalysis concluded that the total incidence of asymptomatic DVT after knee arthroscopy was 9.9% (95% confidence interval [CI], 8.1% to 11.7%), with a proximal DVT incidence of 2.1% (95% CI, 1.2% to 3.0%).[334] Routine use of pharmacologic prophylaxis is probably not warranted, although it would be appropriately considered in a patient with a previous history of VTE or other risk factors, such as prolonged tourniquet time (>60 minutes), a known thrombophilic disorder, or on estrogen therapy.[316]

Trauma

Trauma is the leading cause of death in people less than 40 years of age, and PE is the third most common cause of death in subjects who survive the first 24 hours.[335] A recent analysis of almost 900,000 patients in the National Trauma Data Bank suggests that although the incidence of posttrauma PE is increasing (possibly due to a more liberal use of chest computed tomography scanning), mortality from PE is decreasing, and PE now accounts for the death of about 1 in every 500 patients with trauma.[336]

Up to 60% of trauma patients suffer venographically demonstrated DVT within 14 days of admission,[337] although the range of reported VTE complication rate in trauma varies enormously in the literature, possibly reflecting not only variable study methodologies but also study subject heterogeneity.[338-340] Factors that appear to be independently associated with a greater risk for thrombosis following trauma include (1) age over 40 years, (2) lower-extremity fracture, (3) major head injury, (4) more than 3 ventilator days, (5) venous injury, and (6) major surgical procedure.[336] Although there is general agreement that some form of prophylaxis is routinely warranted, there is confusion (even from prospective randomized clinical trials) whether pharmacologic prophylaxis is superior to nonpharmacologic prophylaxis[341-343] and whether LMWH has a specific advantage over UFH.[335,344] There is general agreement that warfarin should not be used in the acute situation, although it may have a role during the rehabilitation phase in selected patients. Nonpharmacologic methods of prophylaxis may be difficult to apply in some cases with external fixation devices in the lower extremities, and it is therefore recommended that intermittent pneumatic compression alone be used only when both lower extremities are available. Routine surveillance using duplex ultrasound scans are not recommended unless VTE prophylaxis cannot be employed.[295] An extensive review of the scientific evidence and development of evidence-based practice consensus guidelines in trauma surgery published in 2002 recommended that, where feasible, prophylaxis using LMWH rather than UFH be preferred for patients with pelvic, complex lower-extremity, or spinal fractures,[345] especially with partial or complete motor paralysis. However, these Eastern Association for the Surgery of Trauma (EAST) guidelines acknowledge a paucity of Level I evidence to support the prophylaxis algorithms. A subsequent registry of 743 high-risk trauma patients prescribed once-daily prophylactic dose LMWH, regardless of the need for invasive procedures and including those with stable intracranial injuries, did not document any exacerbations of head injury due to bleeding.[346] Notably in this study, the LMWH was initiated an average of 3.3 days after admission. However, for patients at very high risk for both VTE and bleeding with anticoagulation, IVC filter placement—generally using retrievable devices—may occasionally be justified.[347] However, given the lack of randomized controlled trials in this area, it is not surprising that the rate of filter deployment varies widely among major trauma centers.[348]

Even without the associated risks of surgery, bony fracture and immobilization may be sufficient stimuli to increase the incidence of VTE. For example, a 19% rate of venographically demonstrated DVT was noted in patients requiring plaster immobilization or bracing after a leg fracture or ruptured Achilles tendon. This was reduced to 9% in a matched group treated with prophylactic LMWH throughout the period of immobilization.[349] Here again, however, the evidence overall does not clearly support the need for routine pharmacologic VTE prophylaxis in all patients treated for lower-extremity fracture.

Neurosurgery

Patients undergoing neurosurgery involving craniotomy, particularly when performed for high-grade glioma,[350] are also at high risk for VTE. Symptomatic events occur in as many as 6% of patients within the first 3 months postoperatively.[351] In patients with high-grade glioma, the incidence of symptomatic VTE is in the range of 20% to 30%; although the incidence is highest in the first few weeks postoperatively, it does continue throughout the course of the disease.[352] The need for pharmacologic prophylaxis is tempered by the potentially disastrous consequences of intracranial bleeding as a complication of therapy. This concern has led some to recommend a conservative strategy of nonpharmacologic prophylaxis only. However, a landmark randomized placebo-controlled trial demonstrated that enoxaparin 40 mg daily (initiated within 24 hours postoperatively) was associated with a 49% relative risk reduction in venographically demonstrated DVT compared to placebo in patients undergoing elective cranial or spinal surgery (97% for tumors). The rate of symptomatic VTE was reduced from 6% to 1%, with no increase in bleeding. A more recent metaanalysis concluded that a combination of LMWH and intermittent pneumatic compression significantly reduced perioperative VTE risk by 40% without any

increase in intracranial hemorrhage.[353] Yet concerns remain that preoperative or early postoperative administration of LMWH is associated with an increased risk for bleeding.[354,355] In this more than in other areas of surgery, the timing of initiation of heparin/LMWH, dosing, and duration of therapy are critical factors in determining the risk-benefit ratio.[356]

General and Gynecologic Surgery

Rates of asymptomatic VTE in all patients undergoing general surgery without VTE prophylaxis (approximately 20% to 25%) are lower than in major orthopedic surgery, although it should be noted that the rates are substantially lower in certain minor forms of surgery, such as appendectomy or abdominal wall surgery. The increasing use of laparoscopic techniques has tended to lower the risks that were previously encountered with the corresponding open procedures. Patient-related risk factors include cancer, advancing age, a history of previous VTE, obesity, varicose veins, and estrogen use.[294]

In several metaanalyses, thrombosis prophylaxis using LMWH is uniformly superior to placebo and equivalent to subcutaneous UFH.[295,357,358] UFH is also equivalent to LMWH in high-risk urologic or gynecologic surgery. In moderate-risk gynecologic surgery, nonpharmacologic prophylaxis with intermittent pneumatic compression is as efficacious as LMWH,[359] although patients with a history of cancer or DVT or age more than 60 years may be more prone to fail intermittent pneumatic compression alone.[360] Although bleeding rates are purportedly higher with LMWH than UFH in general surgery, this may be a function of administered dose. A lower dose of LMWH (<3500 anti-Xa units/day) may be as efficacious as UFH, with a bleeding rate that is actually somewhat lower.[361]

Cancer increases the risk for postoperative VTE by a factor of approximately 2,[255] and patients undergoing major abdominal or pelvic surgery for neoplastic disorders should be considered to be at high risk. This risk may be related to enhanced activation of coagulation, more prolonged immobilization, and/or greater extent of surgery and duration of anesthesia. Low-dose UFH or LMWH combined with intermittent pneumatic compression appears to be ideal VTE prophylaxis.[361,362] Therapy is typically initiated 2 hours preoperatively. Approximately 40% of VTE occurs following discharge, suggesting a need for prolonged therapy. Indeed, prolonged administration of enoxaparin (40 mg once daily) results in a reduction of venographically demonstrated DVT (from 12.0% in the 1-week treatment group to 4.8% in the 4-week treatment group), without any increased risk for bleeding.[363]

IVC filters are not recommended for VTE prophylaxis in patients undergoing general and abdominal or pelvic surgery.[294] Instead, in the high-risk patient who cannot receive LMWH or UFH, fondaparinux, low-dose aspirin, or mechanical forms of prophylaxis should be considered.[294]

Renal Transplantation

In the United States, approximately 14,000 renal transplants are performed annually. Published estimates of the incidence of postoperative VTE have varied from 0.6% to 25%.[364] A retrospective analysis of more than 2000 renal allograft recipients found a 6.2% incidence of symptomatic DVT in patients undergoing kidney or simultaneous kidney-pancreas transplant without prophylaxis in the period between 1985 and 1995.[365] In this study, the incidence of symptomatic DVT following kidney transplantation (4.5%) did not appear to be significantly higher than the rate in general surgical procedures of a comparable magnitude; however, the rate in patients receiving kidney-pancreas allografts (18.1%) was considered to be excessively high. In another series of 518 transplant recipients, a similar rate of first VTE (9%) was recorded, at a median time of 17 months postoperatively.[366]

A number of special considerations apply to the use of prophylactic anticoagulation in renal transplant recipients. Because renal function may remain impaired for several days or more following the procedure, impaired clearance of LMWHs may increase the risk for bleeding. Therefore UFH may be a better choice for prophylaxis. Furthermore, prophylactic anticoagulation may be of theoretical benefit in the prevention of other vascular complications of renal transplantation. Specifically, it has been demonstrated that common inherited and acquired thrombophilias (factor V Leiden [FV G1691A], prothrombin G20210A mutation, and antiphospholipid antibodies) are associated with an increased risk for primary renal graft thrombosis and acute vascular rejection. Primary renal graft thrombosis, defined as thrombosis of the renal graft vasculature in the absence of histopathologic evidence of rejection, usually occurs within 10 days of renal transplant and virtually always results in loss of the graft. Thrombosis is as likely to be arterial as venous and occurs in approximately 2% (range 1% to 6%) of recipients. The usual presentation is with sudden-onset oliguria or anuria associated with a falloff in graft function. In the case of renal vein thrombosis, there may be pain at the graft site, hematuria, and even graft rupture. A number of retrospective case-control studies[367-369] and a prospective study[370] have demonstrated that one or more of these thrombophilias are associated with an estimated 3- to 10-fold increased risk for renal graft thrombosis.

It has not been established by appropriate prospective randomized study whether antithrombotic prophylaxis can prevent early renal graft thrombosis. However, small series have suggested that UFH, LMWH, or aspirin (>75 mg daily) may diminish the rate of early allograft thrombosis, compared with historical controls.[371,372] Prophylaxis may be particularly vital in high-risk patients, for example, those with identified thrombophilia and/or a previous history of early graft loss or VTE.[373] However, the optimal intensity, duration, and composition of prophylactic regimens has not been determined, and opinions differ considerably, from long-term full-intensity anticoagulation begun in the early postoperative period to short-term lower-intensity heparin followed by longer-term aspirin therapy.[374,375]

COMPLIANCE WITH VENOUS THROMBOEMBOLISM PROPHYLAXIS

Most studies examining the rates of compliance with nationally developed guidelines for VTE prophylaxis have concluded that thromboprophylaxis is underutilized, both in terms of the absolute number of eligible but undertreated patients and the appropriateness (ranging from total omission to suboptimal choice, dose, or duration) of therapy. In the past, orthopedic services tended to be more (>85%) compliant with published guidelines, probably reflecting the longer history of use.[376-378] This pattern may, however, be changing, as orthopedic surgeons are faced with selecting potentially conflicting guidelines.[315] In general surgery in the United States, compliance with grade A recommendations may be much lower, sometimes in the 30% to 50% range.[379,380] This reluctance to use prophylaxis may be explained by a tendency to underestimate the thrombotic risk in high-risk patients.[292,376] Conversely, despite uncertainties regarding the optimal approach to prophylaxis in neurosurgical patients, 85% of practitioners in the United Kingdom regularly used some form of prophylaxis.[381] Improvement in compliance is probably best achieved by the application of guidelines developed by every hospital, including consideration of orders that all patients receive VTE prophylaxis unless they have contraindications.[382] Like all guidelines, the recommendations should be flexible enough to allow informed physicians to exercise their clinical judgment when assessing risks and benefits of a specific regimen in the case of an individual patient.

Treatment of Postsurgical Venous Thromboembolism

The principles of treatment of acute VTE occurring in the postoperative period do not differ materially from treatment under other circumstances (see Chapter 144), with the exception that the bleeding risks associated with anticoagulation are increased. Not surprisingly,

patients who develop postoperative VTE after major orthopedic surgery have a higher risk for mortality, bleeding, and rehospitalization.[383] Although virtually all series agree that recent surgery is a risk factor for bleeding,[384] it is difficult to find relevant literature that quantifies the risk (with respect to the rate of decline in the risk after surgery). It is generally recommended that if surgery has involved a vital organ (e.g., brain, eye), it is inappropriate to risk full-intensity anticoagulation for 5 to 7 days[350] (or longer—e.g., at least 7 to 10 days—when thrombolytic therapy is to be used). This recommendation is supported by animal data demonstrating that the risk for intracranial hemorrhage with full-intensity heparin anticoagulation in the postoperative period following craniotomy dropped off sharply between the 7th and 10th postoperative day.[385] If anticoagulation is strongly contraindicated, placement of an IVC filter may be the only available option. At the other end of the spectrum, anticoagulation after minor procedures in patients judged to be at low risk for bleeding can probably be initiated after 12 to 24 hours. UFH may have certain advantages over LMWH in these circumstances, most notably its short half-life and susceptibility to more complete reversal with protamine, which dictate that it will be more reversible in the event of bleeding.

CHAPTER 162

THE SPLEEN AND ITS DISORDERS

Nathan T. Connell, Susan B. Shurin, and Fred J. Schiffman

Galen described the spleen as the "organ of mystery," with functions related to mood and good or ill humors. It was not until the 18th century that the spleen's relationship to the immune and hematologic systems was appreciated. The complexities of splenic function continue to be the focus of research and observation. Although the spleen is not necessary to life because many of its functions overlap with or can be assumed by other organs, it is an important part of immune and hematologic systems and part of many disease processes. The spleen efficiently phagocytoses erythrocytes, recycles iron, recognizes and destroys pathogens, and induces adaptive immune responses. An appreciation for the subtleties of its anatomy and function is important for the physician evaluating patients with many hematologic, immunologic, hepatic, and infectious diseases.

NORMAL SPLENIC ANATOMY AND FUNCTION

Embryology

The spleen arises from the mesoderm. By the ninth week of gestation, layers of the left dorsal mesogastrium condense and blood vessels appear. Sheaths are formed around arterioles by reticular cells and fibers.[1] Macrophages are present and are phagocytic by the end of the first trimester. Lymphocytes appear during the fourth month, and red and white pulp can be identified by the sixth month. Germinal centers do not develop during fetal life, but primitive inactive follicles are evident at birth. In mice, a homeobox gene, Tlx1 (formerly known as Hox11), which controls the genesis of the splanchnic mesodermal plate, is essential for development of the spleen.[2] Both the basic helix-loop-helix transcription factor capsulin and the Wilms tumor suppressor 1 gene (WT1) are necessary for formation of the spleen. The genetic basis for development of the human spleen is less well understood. The spleen is capable of supporting hematopoiesis during fetal life and, in a variety of pathologic states, postnatally. The circulation of primitive hematopoietic stem cells in peripheral blood during prenatal life through birth makes it difficult to distinguish hematopoiesis arising from stem cells in the spleen as opposed to the incidental presence of hematopoietic cells within the circulation.

Anatomy

The spleen is the body's largest filter of the blood.[3,4] Located directly below the diaphragm and adjacent to the stomach, it is covered by a fibrous capsule with blood vessels, lymphatics, and nerves coated by peritoneal mesothelium. The splenic artery arises from the celiac axis, enters the capsule at the hilum, and branches into trabecular arteries. The trabecular arteries then branch into central arteries and enter the white pulp. The periarterial lymphatic sheath consists of a cuff of T lymphocytes, plasma cells, and macrophages around the central arteries. As the arteries branch, the sheath narrows. B-lymphocyte clusters appear in follicles along the periarterial lymphatic sheath at arterial branch points (Fig. 162-1).

The components of the white pulp are connected by a reticular network and supporting stromal cells. On the cut surface of the normal spleen, white pulp is visible as white nodules 1 to 2 mm in diameter. Their size varies with age and antigenic stimulation. The nodules are fully developed at birth, increase in size in childhood (especially with immunizations and infections), peak at puberty, and involute in adulthood. Immunologically normal, uninfected adults normally have no evident germinal centers. A mantle zone of B lymphocytes surrounds the follicle, or secondary germinal center. Antigen trapping and processing take place in the marginal zone of the white pulp.

The red pulp of the spleen consists of vascular sinuses, the cords of Billroth, and the terminal branches of the penicilliary arteries (Fig. 162-2). Vascular sinuses are lined with $CD8^+$ endothelial cells with long processes and a basement membrane with ring fibers that attach to macrophage-derived dendritic processes. No tight junctions or interdigitations connect the cytoplasmic processes. Intact leukocytes, erythrocytes, and platelets are able to squeeze through the potential spaces between these cells and between the ring fibers (Fig. 162-3). Processes of the reticular cells of the cords of Billroth are outside the sinus walls. Endothelial cells line pulp veins but not the cords.

The reticular structure of the spleen facilitates its immune response. Venous sinus endothelial cells contain a plasma membrane-associated network of stress fibers composed of actin and myosin-like filaments. These filaments may cross the plasma membrane and insert into the mesh-like basement membrane. As the fibers tense, they create fenestrations through which erythrocytes must pass if they hope to continue their journey. Cells infected by parasites or simply worn from age become trapped by the fibers and will not continue in the circulation. This mechanism combined with mannose receptors and Toll-like receptors helps the infrastructure of the spleen play a part in the host's overall immune response.

Circulation of blood through red pulp lined with endothelial cells represents a closed circulation, which is rapid. Circulation into the cords, or open circulation, is slower and permits the macrophages lining the cord to remove damaged or aged cells.

Accessory spleens are present in up to a third of the population and result from failure of precursor cells to fuse during embryologic development. They often receive blood flow from the splenic artery and are located near the spleen but can be distant and confused with a tumor when noted on imaging studies or even physical examination. They can develop similar conditions as the spleen proper and may result in continued abnormalities even after splenectomy.

Functions

The functions of the spleen and their anatomic locations are summarized in Table 162-1.

The Red Pulp

Splenic macrophages dominate the function of the red pulp and are responsible for filtering blood, removing bacteria, and recycling iron.

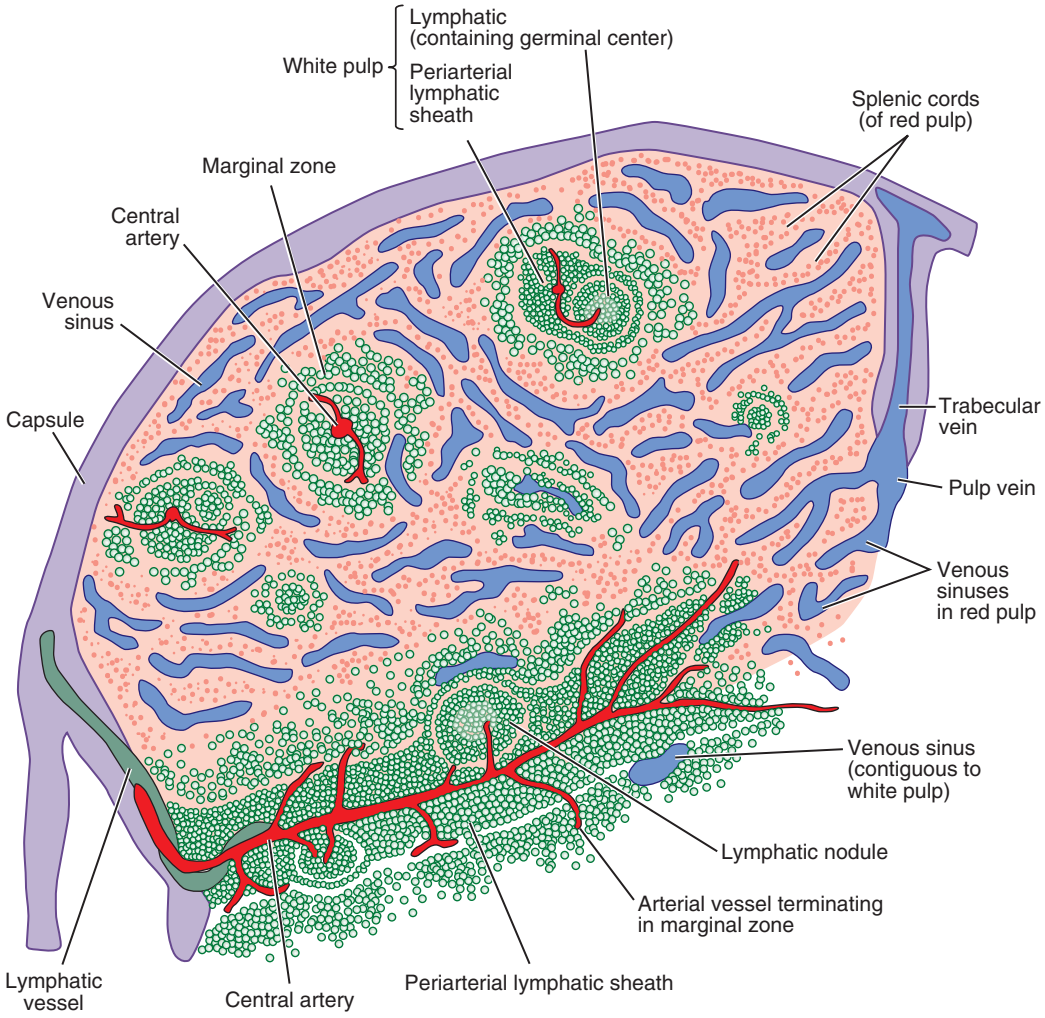

Figure 162-1 ORGANIZATION OF THE HUMAN SPLEEN PRESENTED SCHEMATICALLY. See text for description of blood flow and cell distribution. *(From Emerson SG: Hematopoiesis: The development of blood cells. In Schiffman FJ, editor:* Hematologic pathophysiology, *Philadelphia, 1998, Lippincott-Raven, p 10. Used with permission.)*

Table 162-1 Functions of the Spleen

Category	Function	Effector Cells/Areas
Clearance/Filtration	Antibody-mediated clearance Culling and pitting	Macrophages Reticular meshwork
Immune Response		
Marginal zone	Interaction of antigens with effector cells Antigen processing Immune recognition	Monocytes, lymphocytes Macrophages T cells (periarteriolar sheath)
White pulp	Immunoregulation, antibody production Antigen processing, preservation	B cells (lymphoid follicles) Macrophages
Red pulp	Phagocytosis	Macrophages, monocytes, neutrophils
Hematologic	Hematopoiesis Storage of erythrocytes, platelets, leukocytes Finishing/polishing of erythrocytes	Cords and sinuses Reticular meshwork, red pulp Reticular meshwork, macrophages
Hemostasis	Production of factor VIII, von Willebrand factor	Endothelial cells

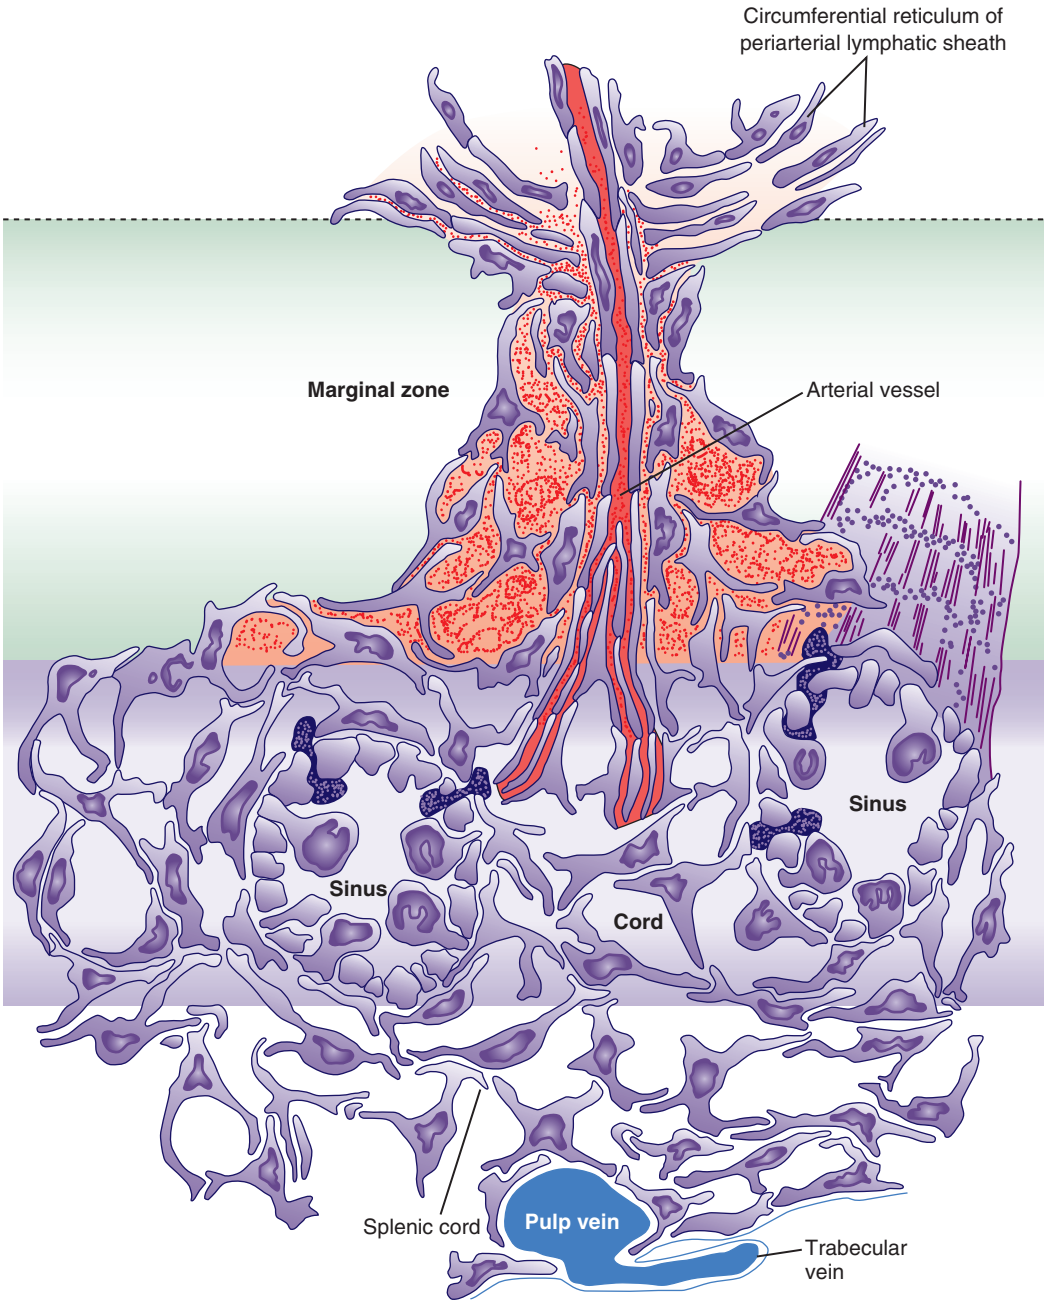

Figure 162-2 DIAGRAM OF THE SPLENIC ARTERY. Arterial blood pools in the splenic cords before entering the splenic sinuses and returning to systemic circulation. *(From Emerson SG: Hematopoiesis: The development of blood cells. In Schiffman FJ, editor:* Hematologic pathophysiology, *Philadelphia, 1998, Lippincott-Raven, p 12. Used with permission.)*

Removal of Damaged and Aged Formed Elements

The venous system of the red pulp enables it to filter whole blood, removing senescent erythrocytes and other blood cells. Arterial blood is delivered to the cords of the red pulp through an open system of reticular fibers, fibroblasts, and macrophages without an endothelial lining. Blood then passes from the cords into the efferent venous sinuses, which are lined with endothelium with a discontinuous structure. Stress fibers extend beneath the basal plasma membrane and run parallel to the axis of the endothelial cells. These cords direct the blood into sinuses through slits modulated in size by the stress fibers. In many animals, these stress fibers and the splenic capsule are contractile and enable the spleen to serve as a reservoir of red cells and reduce blood viscosity when the animal is at rest. In humans, however, there is no evidence that the spleen serves such a function or is capable of significant changes in volume with rest and exercise. To return to the circulation, cells must pass through the slits between venous sinus endothelial cells (see Fig. 162-3), the size of which may be controlled by actin and myosin filaments within the stress fibers in the basal portion of endothelial cells. This surface is probably an important site for the culling and pitting of aged or damaged cells.

As erythrocytes and platelets age, they are less able to tolerate the hostile splenic environment than when they are younger and have a healthy metabolic reserve. The spleen is acidotic (pH 6.8 to 7.2), hypoxic (partial pressure of oxygen [P_{O_2}] 54 mm Hg), and hypoglycemic (glucose concentration approximately 60% of that in venous blood). With age, damaged enucleated cells develop changes in complex membrane carbohydrates; these changes facilitate recognition by splenic macrophages and removal from the circulation. *Culling* describes the destruction of erythrocytes: the normal removal of aging cells or the removal of damaged cells in pathologic states. Most platelets and leukocytes are not removed by the spleen as they

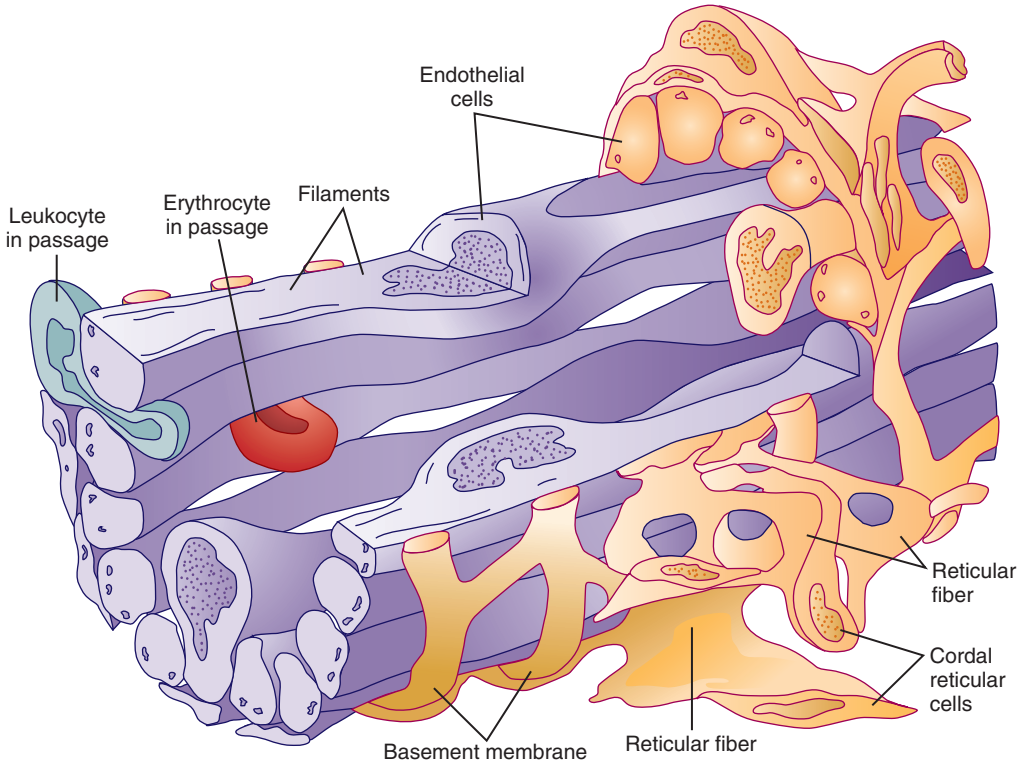

Figure 162-3 ORGANIZATION OF THE SPLENIC SINUSES. Erythrocytes and leukocytes are scrutinized as they squeeze through the reticular fibers of endothelial cells to enter the splenic sinuses. The fenestrae contract and relax according to sympathetic stimuli to regulate cell passage. *(From Emerson SG: Hematopoiesis: The development of blood cells. In Schiffman FJ, editor:* Hematologic pathophysiology, *Philadelphia, 1998, Lippincott-Raven, p 13. Used with permission.)*

age but adhere to vessel walls and migrate into tissues, where they die. *Pitting* refers to the removal of inclusions from within erythrocytes, which are then released back into the circulation. The erythrocyte membrane is in close apposition to the macrophage membrane, so that aged or damaged glycoproteins, antibody, or complement on the surface of the cell are easily recognized and activate phagocytosis. Particulate matter—Howell-Jolly bodies, Heinz bodies, Pappenheimer bodies, and malarial and other parasites—can be removed and the cell returned to the bloodstream. Membrane-containing adsorbed antibody can be removed and the remainder of the cell released with changes in shape and volume. Internal vesicles near the erythrocyte membrane appear as if they were on the surface of the cell and are termed *pits* or *pocks*. The spleen also normally removes these, with the polished erythrocyte returned to the circulation. The lack of this polishing function can be used to assess splenic dysfunction as the number of pits or pocks per erythrocyte is increased when the spleen fails to remove them. The number of cells with pits and pocks is also increased.

Recycling of Iron

Macrophages in the liver and spleen are important for recycling iron as erythrocytes are phagocytized and hydrolyzed in the phagolysosome. Degradation of hemoglobin releases heme, which is catabolized into biliverdin, carbon monoxide, and ferrous iron (Fe^{2+}). Iron is then either released as a low-molecular-weight species for rapid reuse or stored as ferritin. As ferritin accumulates, it aggregates into hemosiderin. Iron-laden macrophages are a feature of iron overload states in both the liver and spleen. Erythrocytes that are destroyed intravascularly release hemoglobin that binds to haptoglobin. CD163 on the surface of splenic macrophages mediates endocytosis of circulating hemoglobin and haptoglobin-bound hemoglobin.

Iron is released from stores in splenic macrophages in response to the erythropoietic drive expressed by the bone marrow. The precise mechanisms are not well understood. Uptake of iron is mediated in most cells by a divalent cation transporter, the natural resistance–associated macrophage protein 2 (NRAMP2), in recycling endosomes that express the transferrin receptor. NRAMP2 transports ferritin into the cytoplasm across the endosomal membrane. In addition to the more widely expressed NRAMP2, macrophages and monocytes express NRAMP1, which was initially described as an iron-transporting protein affecting resistance to intracellular pathogens. A third molecule involved in iron metabolism in the spleen is lipocalin-2, which is secreted by macrophages and other myeloid cells when activated by exposure to bacterial metabolites. Lipocalin-2 binds to bacterial siderophores and sequesters iron from microorganisms. These and other related molecules tightly link the iron-recycling and host resistance functions of the red pulp of the spleen.

Antibody Production

After stimulation and differentiating in the follicles of the white pulp, antigen-specific plasmablasts and plasma cells lodge in the red pulp, where they are closer to macrophages. A similar translocation occurs in lymph nodes, where plasmablasts migrate to the medullary cords. This translocation occurs after upregulation of expression of CXC-chemokine receptor 4 (CXCR4), which binds CXC-chemokine ligand 12 (CXCL12) expressed in red pulp.

The White Pulp

The lymphoid region of the spleen incorporates multiple components of the immune system that are organized to enhance recognition and/or response to pathogens.[5] The white pulp contains lymphoid sheaths around branching arterial vessels, similar to the structure of lymph nodes. Specific chemokines attract B and T cells to their appropriate domains. The periarteriolar lymphatic sheath contains T cells that

interact with dendritic cells and circulating B cells. T cells and dendritic cells are attracted to PALS through CC-chemokine ligands 19 and 21. Clonal expansion of activated B cells occurs in follicles. B-cell migration to follicles requires CXCL13. Expression of all these homeostatic chemokines is reduced when signaling through the lymphotoxin receptor or tumor necrosis factor-α receptor 1 is absent, which results in disorganization of the domains of the white pulp.

Marginal Zone

Leukocytes leave the bloodstream and enter the white pulp in the marginal zone of the spleen via G protein–coupled receptor functions, similar to the migration of leukocytes across endothelial barriers in inflammation. The marginal zone is an area for cells in transit as well as home to resident cells with complex interactions. Marginal zone metallophilic macrophages form an inner ring close to the white pulp, marginal zone macrophages form an outer ring, and dendritic cells and B cells are located between the two sets of macrophages. Both trafficking and retention of dendritic cells and B cells involve complex interactions with integrins and other adhesion molecules.

Innate Immunity

The spleen is important in the recognition of antigens, in the production of antibody, and in the clearance of opsonized and nonopsonized particles from the bloodstream (see Table 162-1). The spleen structure facilitates monitoring of the contents of the blood, with blood flowing through the marginal zone directly along the white pulp. The white pulp is involved in adaptive immunity, whereas the marginal zone is involved in both innate and adaptive immunity (Table 162-2).

Trapping and processing antigens is a major function of the marginal zone. Macrophages are abundant here and the spleen may capture more than 5% of the cardiac output (greater than 250 ml/minute), allowing a large volume of blood to be immunologically scrutinized. Antigens penetrate the germinal center where T lymphocytes predominate. Processing of carbohydrate antigens is a special function of splenic marginal zone lymphocytes. Marginal zone macrophages express lectin receptors and scavenger.

Splenic macrophages are more sensitive to small amounts of opsonic antibody or complement on the surface of particles than are macrophages in the liver, lung, or bone marrow. In the absence of a spleen, individuals may fail to remove bacteria with little opsonic coating, and the production of antigen-specific immunoglobulin (Ig) M is impaired. An asplenic individual has defective recognition of carbohydrate antigens, defective production of IgM early in infection, and defective removal of lightly opsonized particles—all crucial components of response to an invasive infection with encapsulated organisms.

Marginal zone B lymphocytes are sensitive to detection of blood-borne pathogens and rapidly differentiate into either antigen-presenting cells or IgM-producing plasma cells. After activation in the marginal zone, some B cells migrate into the white pulp, where they function to activate naive CD4-positive T cells. Similarly, blood-borne dendritic cells activated in the marginal zone migrate into the white pulp. This process appears to be important in control of certain parasitic infections. For example, in *Leishmania donovani* infection, the spread of infection is inversely proportional to the upregulation or downregulation of CCR7 expression on activated dendritic cells and migration of antigen-presenting cells (APCs) into the white pulp. In human immunodeficiency virus (HIV)–positive patients with low CD4 T-cell counts (less than 300 cells/μL), there is evidence that IgM memory B cell–depletion might be a risk factor for pneumococcal disease. Effective antiretroviral therapy appears to reverse this depletion, in turn decreasing the risk for pneumococcal infection.

Adaptive Immunity

Although the white pulp is both anatomically and functionally similar to lymph nodes, all cells enter the white pulp via the marginal zone rather than through high endothelial venules and afferent lymphatic vessels, exposing them to an environment highly sensitive to detection of blood-borne pathogens. Circulating dendritic cells capture bacteria

Table 162-2 Innate Immune Pattern Recognition Receptors That Are Highly Expressed on Splenic Phagocytic Cells*

Name	Abbreviation	Function	Splenic Cells Expressing	Recognizes or Affects	Pathogens Recognized
Toll-like receptor networks	TLR	Pattern recognition of pathogen-associated molecular patterns	Marginal zone macrophages Dendritic cells	Lipopolysaccharide Flagellin Double-stranded RNA	Multiple bacteria, especially gram negative
Natural resistance–associated macrophage protein-1	NRAMP1	Solute carrier family 11 (proton-coupled divalent metal ion transporters); phagolysosomal function	Macrophages	Lysosomal targeting	*Mycobacterium tuberculosis* *Mycobacterium avium* *Mycobacterium leprae*
Natural resistance–associated macrophage protein-2	NRAMP2	Proton-dependent cation transporter; iron absorption	Macrophages (apical duodenal cells, erythroid cells)	Impairs bacterial gene expression, protein synthesis	*Brucella* spp
Sialic acid–binding Ig-like lectin-1; sialoadhesin	SIGLEC1, CD169	Immunoglobulin superfamily	Splenic and peritoneal macrophages Many hematopoietic cells	Mannose	*Streptococcus pneumoniae*
Specific intercellular adhesion molecule 3–grabbing nonintegrin related 1	SIGNR1, CD209b	ICAM3-binding nonintegrin homologue, mannose receptor	Dendritic cells	Polysaccharide antigens, mannosylated lipoarabinomannan (ManLAM)	Fungi, other pathogens
Macrophage receptor with collagenous structure	MARCO	Type 1 scavenger	Marginal zone macrophages	Lipopolysaccharide	*Staphylococcus aureus* *Escherichia coli*

ICAM, Intercellular adhesion molecule; *RNA,* ribonucleic acid.
*These receptors contribute to resistance to infection with pathogens in the absence of prior exposure, specific immune responses, or surface opsonic immunoglobulin or complement.

from the blood and transport them to the spleen, where they mediate the initial differentiation of B cells to plasmablasts or antigen presenting cells (APCs). Activated APCs entering the white pulp activate T cells, resulting in changes in receptor expression that enable them to migrate to the edge of B-cell follicles. Contact with activated T cells induces an isotype switch in follicular B cells, which then migrate to the red pulp and marginal zones or remain in splenic germinal centers. The white pulp of the spleen is the largest mass of lymphoid tissue in the body. The B lymphocytes, which ultimately produce antibodies, predominate in the nearby germinal centers and mantle zones. These areas all increase in size and activity with immunization or infection. The complex interaction between the cells in close apposition, autocrine and paracrine signaling, and migration of cells into, within and ultimately out of the spleen contributes to the extraordinary repertoire of innate and adaptive immunity within the organ. Changes in splenic architecture are quite dramatic with septicemia; the most marked being depletion of splenic B areas that occurs during overwhelming enterococcemia. Bacterial virulence factors appear to contribute to depletion of B- and T-cell areas.

Hematopoiesis

Active hematopoiesis can be seen in the fetal spleen throughout the second trimester, decreasing during the third trimester. Erythropoiesis and megakaryocytopoiesis predominate, with myelopoiesis present to a lesser extent. As hematopoiesis transitions from the hepatic phase into the bone marrow, it becomes less evident within the fetal spleen. The spleen is not normally a site of hematopoiesis in postnatal life in humans, but it is a rich source of hematopoietic stem cells and can support hematopoiesis in a number of pathologic states. Extramedullary hematopoiesis is a significant cause of splenomegaly primarily in bone marrow disorders (e.g., myelofibrosis or osteopetrosis) and chronic hemolytic anemias (e.g., thalassemia). The stromal cells of the spleen appear to be capable of supporting hematopoiesis and may produce the C-KIT ligand, as do marrow stromal cells. When splenic hematopoiesis occurs, the erythrocytes and platelets that circulate tend to be less mature than when hematopoiesis occurs in the bone marrow, which suggests that egress from the spleen is easier than from the marrow.

In higher mammals, including primates, the resident stem cells are capable of restoring hematopoietic and immunologic function after lethal irradiation.[6]

Stem Cells

Recently the spleen has been shown to be a source of multipotent stem cells in humans as well as other animals. These stem cells have been shown to contribute to the regeneration of multiple types of tissue, including pancreatic islet cells, bone, cranial nerves, and salivary glands. In addition, undifferentiated splenic monocytes assembled in clusters in the cords of the subcapsular red pulp and were shown to accumulate in injured myocardial tissue.[7] These stem cells are considered to have limited potential to undergo malignant transformation.

Storage of Cells

The normal adult human spleen contains 20 to 40 mL of blood and does not serve as a reservoir for blood or erythrocytes. However, in many conditions associated with splenomegaly, especially portal hypertension, the pulp cords widen to create an organ with more storage volume. Vascular pooling of blood and formed elements occurs, regardless of the underlying cause of the splenomegaly. Platelets and granulocytes, however, are normally stored in the red pulp of the spleen. As much as one-third of the total platelet mass may be stored in the spleen and released when cytokines affecting platelet adhesiveness are released. The lack of musculature in the human splenic capsule prevents the distention and contraction that occur in many animals, such as dogs, although the spleen appears to contract in divers during periods of breath-hold apnea. Platelet counts and granulocyte counts rise significantly after splenectomy, then fall. The circulating masses of these cell pools are chronically increased post-splenectomy, which may contribute to an increased incidence of atherosclerosis years after splenectomy.

EXAMINATION OF THE SPLEEN

Maneuvers for examination of the spleen involve inspection, percussion, and palpation, but their sensitivity and specificity vary based on patient factors (such as body habitus) and operator skill.[8] The pretest probability of splenomegaly, based on associated historical and clinical data, influences the positive predictive value of finding splenomegaly on physical examination. If the pretest probability of splenomegaly is less than 10%, then physical examination maneuvers are inadequate for determining the presence or absence of splenomegaly. For those patients with a greater than 10% pretest probability of splenomegaly (for instance, patients with suspected infectious mononucleosis), the examination begins with inspection and then percussion of Traube's space. For adequate examination of the spleen, the patient must be fully supine, relaxed, with arms adjacent to the trunk. Dullness to percussion in Traube's space—defined by the sixth rib superiorly, the anterior axillary line, and the costal margin—should be followed by palpation. Beginning in the right iliac fossa, the examiner's hand gently advances toward the left upper quadrant. This minimizes the likelihood that a grossly enlarged spleen will be missed, and the lower pole and medial border should be easily appreciated. If the spleen cannot be felt with this approach, the left hand of the examiner is placed on the left flank, lifting the lower part of the rib cage to displace the spleen medially toward the examiner's right hand. The splenic notch should be felt in the inferior medial border. Rotating the patient into the right lateral decubitus position while still recumbent may make it easier to palpate the spleen. The spleen should move with deep inspiration. The degree of enlargement is usually measured in centimeters below the costal margin. Depending on the position of the spleen within the abdomen, it may be difficult to appreciate even significant enlargement. Normal splenic size in an adult is up to 250 g and up to 13 cm in its long axis. Up to half of spleens weighing 600 to 750 g are not palpable. Greater degrees of splenomegaly are easier to appreciate on physical examination. In terms of sensitivity and specificity, there appears to not be a difference between examination in the supine position and examination in the right lateral decubitus position.

Up to 15% of normal children and 3% of young adults have palpable spleens, up to 2 cm below the left costal margin, without evidence of illness. The spleen involutes with age, and a spleen that is palpable in an older person is less likely to be a normal variant and more likely to be associated with clinical disease.

IMAGING OF THE SPLEEN

Radionuclide scintigraphy assesses anatomic and functional aspects of the spleen. The most common procedure is a liver-spleen scan in which technetium-99m sulfur colloid is injected intravenously and taken up by hepatic and splenic macrophages. It is the phagocytic activity of macrophages—rather than the presence of the spleen itself or any aspects of lymphoid function—that is assessed. A dynamic ^{99m}Tc scan can also assess the distribution of blood within the portal system and suggest the presence of portal hypertension. Infusion of ^{99m}Tc-labeled or Indium-111–labeled platelets with scintigraphy to determine their relative distribution in the liver and spleen has been used with considerable, but not absolute, success to predict the clinical efficacy of splenectomy in patients with immune thrombocytopenia purpura (ITP).

Ultrasonography readily shows the size, shape, and several aspects of splenic anatomy, including the presence of cysts and abscesses. The

procedure is noninvasive, painless, of low cost, avoids radiation exposure for patients, and is a good screening study when the spleen is thought to be enlarged. In 95% of the normal population, the long axis of the spleen measures less than 12 cm on ultrasound examination. Accessory spleens tend not to be well visualized on routine ultrasonography. In the hands of a skilled operator, endoscopic ultrasound-guided biopsy permits accurate diagnosis of lesions as small as a centimeter or less, which compares well with results obtained using computed tomography (CT). High-frequency sonography has significantly better resolution and can visualize both nodularity within the spleen, which occurs in childhood as immunity is acquired, and accessory spleens and splenosis after splenic rupture or trauma.

CT imaging has the advantage of showing the anatomy and some aspects of splenic function. Contrast material in the stomach, small bowel, and colon, given enterally, helps delineate splenic tissue when it impinges on these organs. Intravenous contrast material is required to delineate splenic lesions whose density is the same as normal splenic tissue. Abscesses have a rim of contrast agent enhancement.

CT can be used to estimate the volume of the spleen. Accessory spleens have the same attenuation as a normal spleen, which is somewhat less than that of liver. Accessory spleens are usually located in the gastrosplenic ligament near the hilum. Subcapsular and intrasplenic hematomas and splenic lacerations are clearly seen on CT. Leukemias and many inflammatory diseases produce diffuse splenomegaly. Granulomas and infarcted areas eventually calcify. Cysts, abscesses, and some malignancies have inhomogeneous patterns on CT scan. Although not replacing other methods of staging, splenic enlargement on CT may direct follow-up studies and indicate prognosis.

In addition to imaging the spleen, CT can be used to direct therapeutic interventions. Abscesses, hematomas, and cysts can be drained (see box on Management of Splenic Cysts). As long as portal hypertension is not present and vascular lesions have been excluded, thin-needle aspiration under CT guidance is generally a safe intervention.

CT scanning of the abdomen, performed as part of the initial emergency department evaluation of patients with abdominal trauma, may avert hospital admission and prevent exploratory laparotomy.[10]

Magnetic resonance imaging (MRI) is useful for identifying vascular lesions, which would otherwise require angiography, and splenic infections. It is more difficult to image the contents of the upper abdomen with MRI than with CT because of respiratory motion. With more rapid imaging technology, MRI has gained considerable utility for imaging infectious and vascular lesions of the spleen. Hepatosplenic candidiasis and other infections to which immunocompromised patients are susceptible can be identified noninvasively with modern MRI technology.

Perhaps the most valuable use of MRI imaging of the spleen is to obtain a quantitative measurement of iron burden in organs that accumulate iron.[11]

Positron emission tomography (PET) scanning using ^{18}F-2-deoxyglucose (FDG) has an increasing role in the diagnosis, staging, and monitoring of lymphoma, both non-Hodgkin and Hodgkin disease. It is more sensitive than CT scanning at identifying nodal disease and superior to both lymphangiography and CT scanning at imaging the spleen. The availability of more sensitive, specific, and less toxic approaches to imaging permits more precise staging of Hodgkin lymphoma without the complications of splenectomy (Fig. 162-4).[12,13]

The role of PET scanning is expanding in other disorders as whole-body PET scanners and appropriate small-molecule markers

Management of Splenic Cysts

A 37-year-old woman with no past medical history comes in for evaluation of early satiety and left shoulder pain. She reports that she feels full after only a few bites of any meal and sometimes becomes nauseated and vomits. Physical examination is remarkable for an enlarged nontender spleen. Imaging shows a large splenic cyst.

- Many conditions can lead to cyst formation in the spleen, including parasitic infections, trauma, hemangiomas, and polycystic kidney disease.
- Asymptomatic nonparasitic cysts may be observed with careful attention and development of a plan for intervention should they become symptomatic, rupture, or become infected.
- Symptomatic cysts may require percutaneous drainage with radiologic guidance or sometimes surgical procedures, including partial or total splenectomy.[9]
- Parasitic cysts should be treated in consultation with infectious disease specialists because the particular parasitic infection, radiologic appearance, and patient comorbidities will guide choice of therapies.

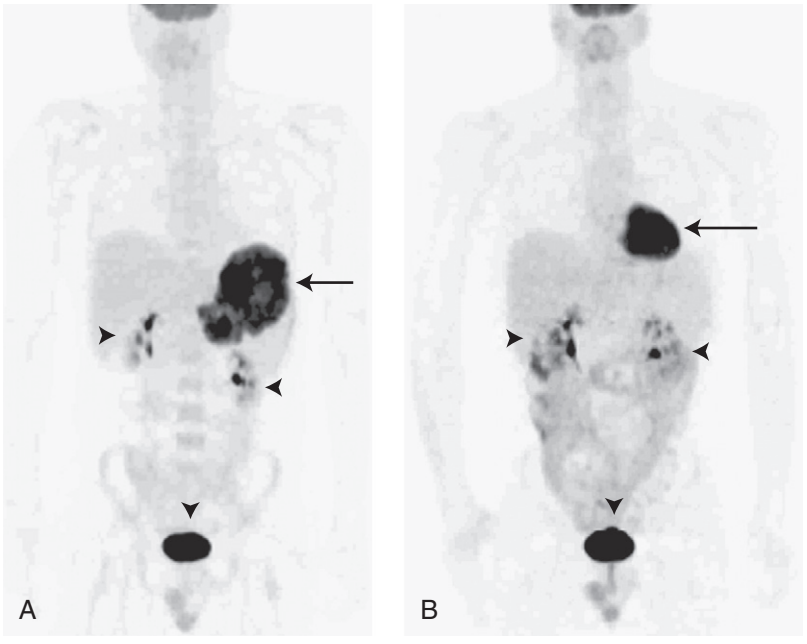

Figure 162-4 PET SCANNING TO IMAGE AREAS OF INVOLVEMENT IN HODGKIN DISEASE. **A,** Pretreatment imaging showing the spleen *(large mass in left upper quadrant with arrow)* and activity in the kidney and bladder *(arrowheads)*. **B,** The same patient after three cycles of chemotherapy. The *arrow* now points to normal activity in the myocardium not seen previously while arrowheads point to persistent urinary tract activity. The spleen is particularly well imaged on PET scan. *PET,* Positron emission tomography. *(From Friedberg JW, Chengazi V: PET scans in the staging of lymphoma: Current status,* Oncologist *8:438, 2003. Used with permission.)*

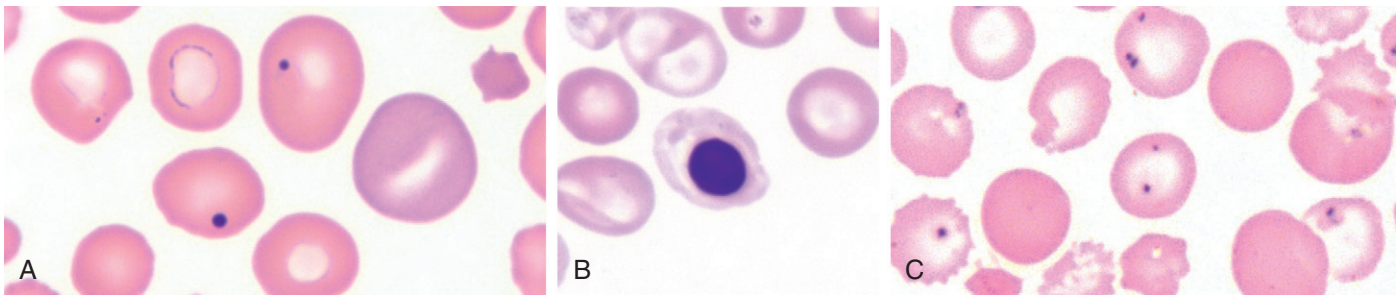

Figure 162-5 RED BLOOD CELL FINDINGS IN HYPOSPLENISM. **A,** Red blood cells with Howell-Jolly bodies. **B,** Nucleated red blood cell. **C,** Cells with Pappenheimer bodies. Red blood cells with Howell-Jolly bodies are seen in patients with hyposplenism. The cytoplasmic inclusions **(A)** are nuclear remnants that are usually round and stain similar to the nucleus of a nucleated red blood cell **(B)**. They occur normally during red cell maturation but are typically removed by a normal spleen. Their presence in the blood indicates less-than-normal splenic function. Pappenheimer bodies **(C)**, which can also be seen in hyposplenism, are siderotic granules that are irregular in shape and frequently multiple.

for individual diseases are more widely available. Imaging studies in small-animal models are very promising; splenic involvement can be identified with high sensitivity in mice.[14]

TESTS OF SPLENIC FUNCTION

The peripheral blood smear may be the most sensitive tool for identification of functional or anatomic hyposplenia. The presence of Howell-Jolly bodies, which are nuclear remnants normally removed by the spleen, is an excellent indicator of hyposplenism (Fig. 162-5). These are rarely seen until the spleen is largely nonfunctional or overwhelmed by other phagocytic functions, such as extravascular hemolysis. Newborn infants commonly have visible Howell-Jolly bodies, and splenic function appears to be at least somewhat impaired in the first week of life. Pappenheimer bodies (siderotic granules normally removed by the spleen) are often seen in hyposplenic states, particularly when a component of hemolysis exists. Erythrocyte morphologic features reflect the lack of membrane polishing by the spleen, with the presence of acanthocytes and target cells. Granulocyte and platelet numbers are increased during asplenic states, including splenic infarction and surgical splenectomy.

To confirm suspected hyposplenism, the simplest test is a count of pitted or pocked erythrocytes. Fixation in 0.5% to 1.0% glutaraldehyde and examination under interference optics should reveal endocytic vesicles containing hemoglobin, ferritin, and remnants of mitochondria. These form in mature erythrocytes and are normally removed by the functioning spleen. The number of pitted cells (not the number of pits per cell) is inversely proportional to splenic function, with normal persons having less than 2% pitted cells.[15] It should be noted that the *absence* of Howell-Jolly bodies on a peripheral blood smear cannot be used as evidence of adequate splenic immune function.[16]

ASPLENIA AND HYPOSPLENIA

Congenital asplenia may be an isolated lesion or associated with severe cyanotic congenital heart disease and bilateral right-sidedness. Life-threatening cardiac lesions, including transposition of the great vessels, pulmonary artery atresia or stenosis, septal defects, anomalous venous drainage, and a single atrioventricular valve, are components of bilateral right-sidedness. The liver is central, and both lungs have three lobes. The peripheral blood smear shows Howell-Jolly bodies and other signs of hyposplenism. There is considerable variation in the anatomic and functional findings, and it is difficult to predict with accuracy the degree of splenic dysfunction on the basis of the anatomy alone. Children who survive the cardiac difficulties in the neonatal period have a significant incidence of sepsis secondary to a variety of organisms.

Polysplenia is associated with bilateral left-sidedness. Dextrocardia, bilateral superior venae cavae, septal defects, and anomalous pulmonary venous return are associated cardiac lesions. Both lungs have two lobes, the liver is midline, and bowel malrotation is common. The splenic tissue is divided into two to nine masses. The peripheral blood smear usually does not suggest hyposplenism, and no clear association with an increased risk for infection has been documented.

Asplenia occurring without heart disease is less likely to be detected before an infection develops than when associated cardiac lesions bring the patient to medical attention. Some of these patients also have situs inversus. Isolated cases of asplenia discovered after death of an otherwise healthy adult or child from overwhelming sepsis with encapsulated organisms have been reported. Familial instances of congenital asplenia are likely to be instances of genetic abnormalities (e.g., Hox11/Tlx1), but these have not yet been documented. Examination of a blood smear for Howell-Jolly bodies is a simple procedure and may be lifesaving in the rare patients affected with these disorders.

If Howell-Jolly bodies are observed on the blood smear of an otherwise healthy person, imaging should be performed to assess for the presence of a spleen. Immunization with polysaccharide vaccines and early intervention with antibiotics for apparent infection may prove lifesaving for these individuals. Because approximately 20% of invasive pneumococcal infections in these patients are nonvaccine strains, a high degree of vigilance remains essential, even with more widespread immunization of healthy children.

ACQUIRED HYPOSPLENISM

Infarction in Sickle Cell Disease

The course of sickle cell disease is marked by progressive dysfunction of multiple organs over many years, and one of the earliest organs to be affected is the spleen. Serial measurements of the numbers of pitted erythrocytes in patients with sickle cell disease demonstrate that splenic dysfunction develops progressively over the first few years of life in the major sickle syndromes (Figs. 162-6 and 162-7). The hypoxic, acidotic, hypoglycemic environment of the spleen creates optimal conditions for tactoid formation and for sickling of the poorly deformable erythrocytes, which then block splenic blood vessels and infarct the tissues. Splenic environmental conditions that enhance acidosis or hypoxia, or additional erythrocyte membrane or enzyme abnormalities that promote irreversible sickling, increase splenic infarction. The hyposplenism is reversible with transfusion for at least the first few years of life but becomes irreversible with progressive damage to blood vessels by 6 years of age in patients with sickle cell disease.

Splenic sequestration is a manifestation of the infarctive process of sickling in the spleen that extends to involve larger veins. Distensible splenic tissues results in pooling of a large amount of blood, whereas the venous drainage is occluded by sickled hypoxic erythrocytes. Patients with sickle cell disease who have not yet had multiple episodes

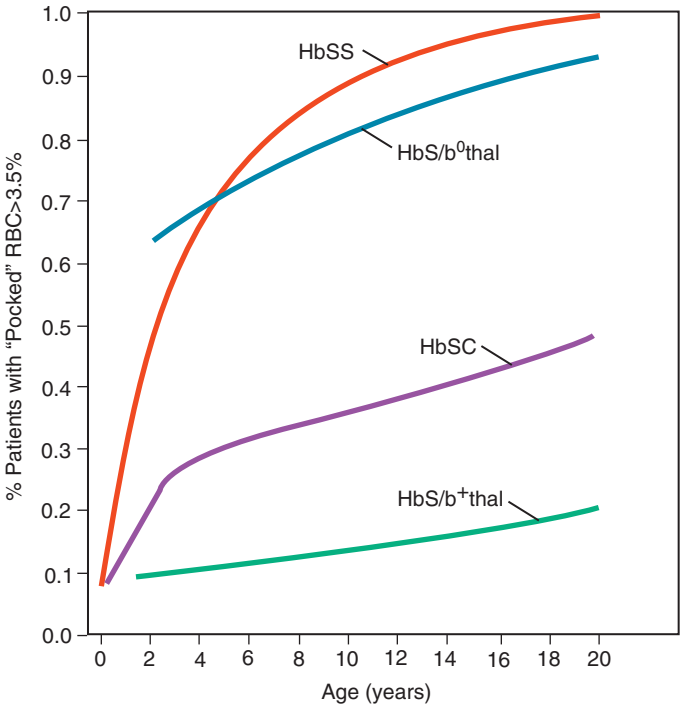

Figure 162-6 DEVELOPMENT OF FUNCTIONAL ASPLENIA IN SICKLE CELL DISORDERS. *(From Pearson HA, Gallagher D, Chilcote R, et al: Developmental pattern of splenic dysfunction in sickle cell disorders,* Pediatrics *76:392, 1985. Used with permission.)*

Figure 162-7 POCKED ERYTHROCYTES IN THE SICKLE HEMOGLOBINOPATHIES. *(From Sills R, Oski FA: RBC surface pits in the sickle hemoglobinopathies,* Am J Dis Child *133:526, 1979. Used with permission.)*

of infarction and whose spleens have not undergone fibrosis are susceptible to this syndrome. Unlike the chronic process of smaller-vessel infarction, the acute splenic sequestration crisis can be life threatening because a large amount of blood can collect in the highly distended spleen. The tendency to recurrence and the potential for fatal outcome lead to the Propensity for recurrence and the high-associated morbidity and mortality has resulted in the common recommendation for splenectomy in a patient who has had one severe splenic sequestration crisis, or more than one less severe crisis. Occlusion of venous drainage also occurs in the liver, but the less distensible capsule of the liver and the options for venous drainage through the portal system make this less likely to threaten life.

Immunologic and Autoimmune Diseases

Poor phagocytic function of the spleen is associated with impaired function of the Fc receptors on splenic macrophages in a variety of immunologic, rheumatic, and inflammatory disorders. Among those disorders in which hyposplenism has been clearly defined and associated with a risk for infection are systemic lupus erythematosus, rheumatoid arthritis, sarcoidosis, systemic vasculitis, ulcerative colitis, celiac disease, amyloidosis, chronic graft-versus-host disease, mastocytosis, and congenital and acquired immunodeficiency. The diseases themselves and the immunosuppressive therapies that are used in their management may contribute to the risk for infection in these conditions. Immunization with polysaccharide antigens and recognition of the risk of bacterial infection are important steps in reducing the risks of splenic hypofunction.

Splenomegaly and the production of autoantibodies (such as to platelets) are features of the acquired immunodeficiency syndrome (AIDS). In the late stages of AIDS, atrophy of lymphoid follicles and depletion of T cell–dependent areas are common. It is not clear that impairment of phagocytic function is a component of splenic atrophy in AIDS.

Therapy-Induced Splenic Hypofunction

Radiation therapy affects splenic function depending on the dose administered. In general, phagocytic cells are not affected by irradiation, but lymphoid cells are extremely sensitive. B-cell function is nearly ablated with as little as 500 cGy. T-cell lymphoblastogenesis is eliminated by administration of 3000 cGy. With doses of 2000 cGy, splenic hypofunction is usually transient because the macrophages and splenic stroma are not affected, and circulating B and T lymphocytes can repopulate the splenic follicles. Permanent splenic hypofunction may develop with doses of 4000 cGy or higher. The risk for infection is significant after such therapy.

Corticosteroid therapy impairs the affinity of the Fc receptors of splenic macrophages for opsonized IgG and decreases the adhesiveness of granulocytes and monocytes. This can result in an acute pharmacologic splenectomy, even at commonly administered therapeutic dosages. The function of the Fc receptors on hepatic, pulmonary, and bone marrow macrophages is far less affected than that of splenic macrophages. The acute rise in platelet count or hemoglobin values seen with corticosteroid therapy in ITP or autoimmune hemolytic anemia is due to decreased clearance of sensitized cells. With prolonged therapy, the production of antibodies by splenic lymphocytes is also affected, and splenic function continues to be impaired.

Intravenous IgG appears to decrease the phagocytic function of the spleen by binding to Fc receptors and impeding their recognition of opsonized particles. This is a transient effect because the Fc receptors are internalized and recycled, and opsonic function returns to normal within 2 to 3 weeks. Occupancy and impairment of function of Fc receptors is also seen with administration of anti-D immunoglobulin to Rh-positive patients, which induces a transient hemolytic anemia. Reticuloendothelial blockade, or occupancy of these receptors, refers to the impaired ability of the spleen to recognize and remove other IgG-coated particles, including bacteria, in the presence of these agents.

SPLENOMEGALY AND HYPERSPLENISM

An enlarged spleen is not a disease state in itself but usually indicates some underlying pathologic state.[17] The processes run the gamut from

Timing of Return to Contact Sports in Athletes Who Have Had Infectious Mononucleosis

A 17-year-old male high school student is diagnosed by his primary care physician with infectious mononucleosis. The patient is concerned about the upcoming soccer season and wants to be able to start training with the team in 4 weeks.

- More than half of patients with infectious mononucleosis develop splenomegaly within the first 14 days of illness.
- Most reports of splenic rupture in the setting of infectious mononucleosis occur in the first 21 days of illness.
- There is a paucity of data to support imaging the spleen to document resolution of splenomegaly before returning to contact sports.
- Noncontact sports may be safely resumed after at least 21 days from the onset of initial symptoms, and contact sports should be safe in most cases after at least 28 days. Infectious mononucleosis–associated splenic rupture has been reported as far as 7 weeks after symptom onset.
- The timing of return to sports and the risks should be discussed with the patient, especially if the patient may not have returned to baseline after prolonged fatigue.

minor to life threatening, from congenital disorders to those at the end of life. It is useful to approach the differential diagnosis of splenomegaly by considering the processes that may cause splenic enlargement and then to focus on the specific diagnoses within those categories. The spleen may be enlarged as a result of infiltration, hypertrophy of normal elements (macrophages and lymphoid components), extramedullary hematopoiesis, inflammatory or immunologic processes, and systemic or portal congestion (see box on Timing of Return to Contact Sports in Athletes Who Have Had Infectious Mononucleosis). The degree of splenomegaly correlates well with involvement of the spleen in many malignant disorders, such as Hodgkin disease. Rarely, anatomic abnormalities will cause splenomegaly. Splenomegaly is important to investigate because it is frequently the presenting finding of a serious disorder whose earlier recognition and treatment may prevent significant long-term morbidity and mortality. The diseases associated with splenomegaly are detailed in Table 162-3. Patients with splenomegaly do not necessarily have hypersplenism, and patients with hypersplenism may indeed have normal-sized spleens, such as those seen in ITP.

Hypersplenism refers to nonimmune, indiscriminate destruction of the formed elements of the blood by a spleen that is usually enlarged, affected by portal hypertension, or both. The bone marrow is hyperplastic, and the peripheral blood cell counts are decreased as a consequence of destruction of mature formed elements. Splenectomy corrects the cytopenia. Any of the formed elements of the blood—erythrocytes, neutrophils, or platelets—can be affected, alone or in combination. Splenic hypertrophy in cirrhosis is due to an increase in splenic macrophages and their activity. Because a normal function of splenic macrophages is to remove senescent cells, this is an exaggeration of a physiologic process.

Hypersplenism develops in patients who receive chronic transfusions. There are several components that contribute to the development of hypersplenism. The antigenic load of allogeneic transfused cells stimulates the immune system. Transfused cells have shorter survival than normal red cells (mean of 60 instead of 120 days, unless specially prepared neocytes are used), which increases the work of splenic macrophages. Finally, iron overload causes hemosiderosis of both the spleen and the liver, so that portal hypertension may develop and further increase splenic pathology. Hypersplenism increases the transfusion requirement in patients who are already transfusion dependent.

Table 162-3 Causes of Splenomegaly

Primary Process	Pathogenesis	Examples
Anatomic	Developmental abnormalities	Cysts, pseudocysts, hamartomas, peliosis, hemangiomas
Hematologic	Hemolysis	Intrinsic (membrane, enzyme, hemoglobin disorders), extrinsic (immune)
	Extramedullary hematopoiesis	Myeloproliferative diseases/ myelodysplasias, myelofibrosis, osteopetrosis
Infectious	Bacteria	Acute and chronic systemic infection, abscesses, subacute bacterial endocarditis
	Mycobacteria	Miliary tuberculosis
	Spirochetes	Syphilis, Lyme disease, leptospirosis
	Viruses	Epstein-Barr virus; cytomegalovirus; human immunodeficiency virus; hepatitis A, B, C
	Rickettsia	Rocky Mountain spotted fever, Q fever, typhus
	Fungi	Disseminated candidiasis, histoplasmosis, South American blastomycosis
	Parasites	Malaria, babesiosis, toxoplasmosis, *Toxocara canis, Toxocara cati*, leishmaniasis, schistosomiasis, trypanosomiasis
Immunologic	Collagen vascular diseases	Felty syndrome, systemic lupus erythematosus, mixed connective tissue disorder, systemic vasculitis, Sjögren syndrome, systemic mastocytosis
	Immunodeficiency	Common variable immunodeficiency
	Immune/ inflammatory	Graft-versus-host disease, serum sickness, large granular lymphocyte lymphocytosis, Weber-Christian panniculitis
Neoplastic	Primary malignancies	Lymphomas, leukemias
	Metastatic malignancies	Breast, lung, skin, colon
Infiltrative	Storage diseases	Gaucher disease, Niemann-Pick disease, GM_1 gangliosidosis, glycogen storage disease type IV, Tangier disease, Wolman disease, mucopolysaccharidoses, hyperchylomicronemia types I and IV
Congestive	Portal hypertension	Intrahepatic cirrhosis, extrahepatic cirrhosis (Budd-Chiari syndrome)
	Systemic	Congestive heart failure
	Local	Splenic vein thrombosis

SPLENECTOMY

Indications and Timing

Splenectomy should be performed for clinical indications rather than for specific diagnoses. In many instances, removal of the spleen will improve the condition of patients with hemolytic anemia due to intrinsic disorders of erythrocyte membranes and enzyme disorders, and of those with chronic conditions, such as storage diseases and

portal hypertension. Specific clinical indices that require intervention should be identified, and parameters that can be used to identify clinical improvement (usually an increase in peripheral blood cell counts, growth, or energy level) should be determined before the procedure is performed. For patients with inherited erythrocyte membrane or enzyme disorders, such as hereditary spherocytosis or pyruvate kinase deficiency, marked reticulocytosis indicating significant metabolic energy required for erythropoiesis, somatic growth failure, or lack of exercise tolerance would be potential indications for splenectomy. Avoidance of formation of gallstones, formerly often considered an indication for splenectomy when a diagnosis of hereditary spherocytosis was made, is less important today because minimally invasive surgical procedures have improved the management of cholelithiasis. Patients with storage disorders such as Gaucher disease with splenomegaly and hypersplenism develop cytopenias requiring intervention. The clinical benefit to be obtained from splenectomy should at least balance, and preferably outweigh, the potential long-term risks of postsplenectomy septicemia, an increased risk for thrombosis, and the shift of storage cells from the spleen to other organs, such as the bone marrow, where they may do more harm in the absence of the spleen. Not all patients with hemolytic anemias, require splenectomy. If such patients develop an aplastic crisis due to parvovirus B19 infection while their spleens are intact, they may require a transfusion. Many patients with mild chronic hemolysis and well-compensated anemia may be better off with their spleens remaining intact. Patients with ITP should undergo surgical splenectomy when the risks of bleeding or of medical therapies (such as long-term corticosteroids) are such that the benefits of splenectomy exceed the risks. The indications for splenectomy are different in adults than in children and are affected by the presence of underlying disorders, such as systemic lupus erythematosus and HIV. In an attempt to avoid immunologic consequences of a total splenectomy, several centers are performing partial splenectomies for hereditary spherocytosis, although in some cases a second procedure is later required.[18]

Splenectomy for sickle cell disease is usually performed for splenic sequestration that is severe, persistent, or recurrent. In some sickle syndromes, the spleen does not autoinfarct in childhood, and persistent splenomegaly may increase the degree of anemia. The risk for subsequent development of gallstones should be considered in patients with hemoglobinopathies and other hemolytic anemias so that cholecystectomy can be performed simultaneously, if deemed indicated.[19]

The timing of splenectomy—when it is to be performed—should again be chosen to minimize risks and maximize benefits. Immunity to carbohydrate antigens, such as those in the cell walls of encapsulated organisms such as *Streptococcus pneumoniae, Neisseria meningitidis,* and *Haemophilus influenzae* type b, develops over the first 2 to 3 years of life. When splenectomy can be delayed until the patient is at least 2 and preferably more than 5 years of age, specific immunity and response to administered polysaccharide vaccines will improve host defenses and lessen the risk for postsplenectomy sepsis. When patients have a disease, such as Gaucher disease, or hemolytic anemia predisposing to iron overload, such as thalassemia, the presence of the spleen as a preferential site for the storage of harmful cellular breakdown products may protect other organs from damage. Delaying splenectomy until a clear clinical indication is present will balance risks and benefits to an optimal degree.

Surgical Options

When splenectomy is clearly indicated, acute complications are rarely a consideration in the decision to perform surgery. Nevertheless, advances in surgical procedures have minimized the short-term risks of the procedure itself and of postoperative complications, such as intestinal obstruction from adhesions. Subtotal splenectomy can be performed when total splenectomy is not desirable, such as for the removal of a cyst, a pseudocyst, or tumors, after trauma, or for Gaucher disease. Wedge resection with mattress sutures and cyanoacrylate adhesions and microfibrillar collagen omental packs have greatly improved partial splenectomy procedures in the past decade. Laparotomy is required when extensive peritoneal adhesions are present and for removal of massively enlarged spleens. A sufficiently large incision to permit full visualization and mobilization is essential when the spleen is very large or when inspection is a major part of the surgical procedure. A retroperitoneal approach is useful when the spleen is not massively enlarged but needs to be fully removed, such as when cytopenias are the indication for the procedure. This approach shortens the postoperative recovery time and avoids induction of peritoneal adhesions.

Minimally invasive procedures have become standard for most splenectomies. Laparoscopy is now the procedure of choice for splenectomy. Although the operative time is significantly greater than for laparotomy, the postoperative recovery time, the risk for damage to the pancreas, the likelihood of developing a subphrenic abscess and peritoneal adhesions postoperatively, and the nutritional and metabolic challenges to the patient are considerably reduced. Laparoscopic splenectomy can be performed even in thrombocytopenic patients. The outcome of laparoscopic splenectomy in ITP is affected by the experience and skill of the surgeon and by the patient's obesity. Prolonged presurgical use of corticosteroids may induce obesity and impair tissue healing, resulting in a higher risk for complications from laparoscopic splenectomy than when splenectomy is performed before the adverse drug effects develop.

Appreciation of the risk for postsplenectomy septicemia and refinements in noninvasive, accurate radiologic monitoring techniques have led to more conservative approaches to splenic injury. Nonoperative management has increased over time and has an acceptable mortality and complication rate in selected patients, although early discharge may put patients at risk for the later complications.[20] Noninvasive imaging and minimally invasive surgical procedures have greatly affected these trends. After traumatic rupture, splenic tissue may regenerate minisplenules in the peritoneal cavity, a process termed *splenosis*. Although splenosis appears to be partially protective against overwhelming postsplenectomy infection in animals, its protective value in humans is not known and may depend on the adequacy of splenic tissue perfusion. If poorly vascularized, the ectopic splenic tissue may not provide adequate contact between macrophages and the antigens of the infecting organism. It is generally valuable to attempt preservation of splenic function when possible after traumatic rupture. Some surgeons attempt to induce splenosis when traumatic splenectomy is unavoidable, in the hope of minimizing late complications.

As the late complications of splenectomy are better appreciated, surgeons have become increasingly creative at performing procedures that preserve or restore splenic function. Even large cysts that were indications for splenectomy until recently have been managed with spleen-conserving procedures, such as partial or total cyst removal, which can often be performed laparoscopically.[21] Pancreatic surgery often requires sacrifice of the spleen; however, increasing numbers of procedures are being performed with salvage of the spleen.[22,23]

Splenic transplantation is being used as a means of developing immune tolerance, as well as a means of reducing the risk for infection following organ transplantation.[24] Allograft spleen has been transplanted within multivisceral grafts with only minimal graft-versus-host disease. To date there are more animal than human data, and it is unclear how large an impact this approach will have on visceral, especially small bowel and pancreatic, allotransplantation.[25] If protection against infection is the main consideration, an intact spleen is superior to a repaired or autotransplanted spleen, whereas accessory spleens and splenosis may be only marginally better than asplenia.[16]

Complications After Splenectomy

Acute complications in the perioperative period include rupture of the spleen, the development of a subphrenic abscess, and injury to the pancreas during the operative procedure. In a healthy patient, the immediate risk of splenectomy is limited. The degree of splenomegaly

greatly affects the risk for rupture and pancreatic injury. The technical difficulty of performing a splenectomy is much greater when the spleen is massively enlarged than when the spleen is small. Rupture of the spleen once the arterial supply has been ligated is rarely a problem. The splenic hilum is retroperitoneal, so if the spleen is very large, mobilization to gain access to the splenic artery and vein can be difficult. After recovery from surgery, intestinal obstruction due to formation of peritoneal adhesions is a complication that, if it is to occur at all, usually occurs within the first few months.

Two late complications of splenectomy give the greatest concern: overwhelming postsplenectomy septicemia and atherosclerotic heart disease. Both of these complications may develop many years after the splenectomy (Fig. 162-8). The precise risk is not known, and preventive interventions are probably underused because patients may not be aware of the risks of splenectomy performed early in life.

Postsplenectomy septicemia is rare but may be rapidly lethal. In the absence of protective levels of opsonic IgG antibodies produced in the spleen, hepatic and pulmonary macrophages are unable to effectively clear organisms from the bloodstream. Organisms that enter the bloodstream and would ordinarily be removed by splenic macrophages are able to evade recognition by macrophages whose Fc and C3b receptors appear to be less avid than those of splenic macrophages. Circulation of the blood through the liver and lung is more rapid than through the spleen, and there is little opportunity for macrophages to recognize organisms with surfaces containing little IgG and only small amounts of C3bi. The important filtration function of the venous sinus endothelial cells is absent following splenectomy. The generation of cytokines, including tumor necrosis factor-α, and bacterial endotoxins leads to cardiovascular collapse and shock. It is rare to revive an asplenic patient once the patient is in shock, even with effective antibiotic therapy. The risk that this will happen varies with the indication for splenectomy (Table 162-4) and the patient's medical condition. Factors that impair host defenses significantly increase the risk for infection. These include deficient opsonins (hypogammaglobulinemia and specific antibody production deficiency), reticuloendothelial blockade related to increased phagocytic activity of macrophages in other organs, impaired antigen processing or recognition (AIDS, lymphoma, other malignancies, and some collagen vascular diseases), neutropenia, and high iron load (thalassemia). The tetrapeptide tuftsin, primarily produced in the spleen, enhances the phagocytic activity of monocytes and neutrophils; its absence in asplenic patients appears to contribute to depressed neutrophil function and the subsequent increased risk for infection.

Patients at the lowest risk for overwhelming postsplenectomy sepsis are those in whom splenectomy cures the underlying problem, such as isolated ITP, hereditary spherocytosis, and trauma. Patients undergoing splenectomy for trauma have a 50-fold greater risk for subsequent septic death than trauma patients with spleens intact, whereas the risk in patients with sickle cell disease is increased 350-fold over that of the general population, and other authors report the risk to be 600 times greater.

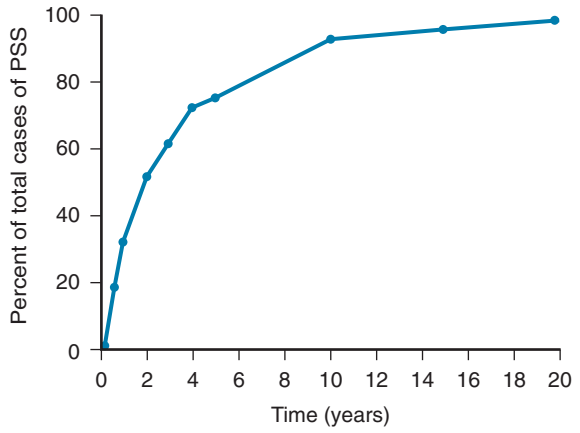

Figure 162-8 THE INTERVAL FROM SPLENECTOMY TO POST-SPLENECTOMY SEPSIS (PSS). Of the total (N = 288), 3.1% occurred more than 20 years after splenectomy. *(From Lutwick LI: Infections in asplenic patients. In Mandell GL, Bennett JE, Dolin R, editors:* Principles and practice of infectious diseases, *ed 7, Philadelphia, 2009, Churchill Livingstone. Used with permission.)*

An increased risk for vascular complications may result from splenectomy. Acute portal vein thrombosis occurs within 2 months of splenectomy in 5% to 37% of patients, which is probably the result of local surgical factors. Patients with thalassemia and prior splenectomy appear to also have an increased incidence of venous thromboembolism beyond the portal venous system. In addition, splenectomy appears to be a risk factor for the development of pulmonary hypertension. Vascular events after splenectomy are likely multifactorial in origin, being attributed to a combination of hypercoagulability, platelet activation, activation of endothelium due to the persistence of particulate matter, and damaged cells in the bloodstream.

Atherosclerosis that develops many years after splenectomy in patients with hereditary spherocytosis or hereditary stomatocytosis may be related to subsequent thrombocytosis that leads to enhancement of plaque formation. Statistically the increased risk for atherosclerosis is not great, but for individuals with other risk factors, such as hypertension, diabetes, high levels of cholesterol or homocysteine, heterozygous protein C or S deficiency, or factor V Leiden, splenectomy may pose a more significant risk. Although no human data are currently available in this area, some studies have suggested that the spleen might be involved in lipid metabolism in both rats and rabbits.

Prevention of Complications

Postsplenectomy Septicemia

The major risk for postsplenectomy sepsis is infection with encapsulated organisms such as *Staphylococcus pneumoniae, Haemophilus influenzae* type b, and *Neisseria meningitidis,* which require opsonization for effective phagocytosis. Polysaccharide vaccines are available for all three bacteria.[26,27] The highest risk period for children is in the first 2 years of life, when their ability to mount an antibody response to purified polysaccharides has not developed completely, so protein-conjugated vaccines are now in widespread use. This has significant potential benefit for patients when asplenia is not recognized, because they might then be immunized as part of their routine care. The antibody responses to vaccines, especially the conjugated vaccines, differ in IgG subclasses from those produced following natural infection. Overwhelming postsplenectomy sepsis and death from sepsis in functionally hyposplenic patients should be preventable.[28] It is recommended that immunization be done 2 to 3 weeks before the anticipated splenectomy to optimize antigen recognition and processing and induce more effective immunity. If emergency

Data from Gorse GJ: The relationship of the spleen to infection. In Bowlder AJ, editor: *The spleen: Structure, function, and clinical significance,* New York, 1990, Van Nostrand Reinhold, p 269, with permission.

Vaccination of a Patient Scheduled for Elective Versus Emergency Splenectomy

A 50-year-old man with refractory immune thrombocytopenia purpura is scheduled for splenectomy. Having heard that there is a risk for different types of infection after splenectomy, he asks what he can do to reduce his risk.

Patients scheduled for elective splenectomy should receive the following at least 14 days before the procedure:

- *Streptococcus pneumoniae* vaccine
- *Haemophilus influenzae* vaccine
- *Neisseria meningitis* vaccine

Consider administration of the influenza vaccine because influenza is a risk factor for secondary bacterial infection.

If the procedure is done emergently, wait until at least the 14th postoperative day.

splenectomy is performed, it is recommended that vaccination be postponed until at least 2 weeks postsplenectomy to avoid the transient immune suppression often seen with general anesthesia and surgery (see box on Vaccination of a Patient Scheduled for Elective Versus Emergency Splenectomy). Adults are generally presumed to be immune to *Haemophilus influenzae* type b and may receive the 23-valent pneumococcal polysaccharide vaccine (PPSV23) and meningococcal vaccines alone. Reimmunization for children is recommended 2 to 5 years after initial immunization. Splenectomized adults should be revaccinated with the PPSV23 once after 5 years, whereas meningococcal revaccination should occur every 5 years. Conjugating polysaccharides to pneumococcal surface peptides may offer a novel approach. Because these recommendations change with experience and vaccine use, it is wise to consult current guidelines for individual patients. Additional organisms to consider in postsplenectomy sepsis include *Escherichia coli, Pseudomonas aeruginosa,* and *Capnocytophaga canimorsus*.[29]

There are fewer data on the efficacy of prophylactic antibiotics for asplenic patients, except for young children with sickle cell disease, in whom antibiotics should be initiated as soon as the diagnosis is established. Present recommendations are that twice-daily oral penicillin V potassium or amoxicillin be continued in sickle cell patients until 5 years of age or 3 years postsplenectomy. High-risk patients with surgical or functional asplenia, including those with diagnoses of thalassemia, Hodgkin disease, other malignancies, immunodeficiency disease, or chronic graft-versus-host disease, should receive prophylactic antibiotics unless specific contraindications exist. Patients who have a history of pneumococcal postsplenectomy sepsis may be considered candidates for lifelong daily prophylaxis as well. Whether or not such patients receive prophylactic antibiotics, and regardless of their immunization status, they may develop overwhelming infections with other organisms, including gram-negative organisms and *Staphylococcus aureus*. Updated recommendations should be consulted for specific circumstances.

The single most important measure to prevent postsplenectomy septicemia is education of the patient, family, and physician. Recognition of the risk, the institution of appropriate preventive measures, and the rapid administration of antibiotics to a patient who is showing signs of infection (fever and chills) can be lifesaving. Some experts recommend that at the time of febrile illness, asplenic patients take immediate antibiotics at home before quickly traveling to an emergency room for evaluation.

Atherosclerosis

The magnitude of the risk for development of atherosclerosis is not clear.[9,30,31] Appropriate preventive measures include identifying and minimizing concurrent risk factors, such as obesity, dietary patterns, a sedentary lifestyle, and the presence of other hereditary factors that would predispose to thrombosis. Low-dose aspirin could be considered, but no data exist regarding its efficacy in this situation.

CONCLUSIONS AND FUTURE DIRECTIONS

Although very little novel information has emerged about clinical aspects of splenic function in recent years, appreciation of many subtleties of splenic function and advances in supportive care in several fields have had significant impacts on the management of disorders of the spleen. Better education and more effective immunizations have helped prevent serious complications related to splenic disorders. Advances in imaging and surgery have transformed the diagnosis and management of congenital and traumatic splenic disorders.

Enhanced understanding of the complexity of communication interaction between the cells of the immune and hematopoietic system has improved our appreciation of the molecular, cellular, system, and network basis for clinical observations about splenic function. The ability of splenic macrophages, in concert with dendritic cells and B cells, to recognize and ingest a variety of microorganisms—even in patients without previous exposure to the pathogens—provides great insight into the reasons that the spleen provides protection against a variety of very specific infections. More detailed understanding of the impact of the splenic microenvironment on cellular functions, the role of stromal infrastructure on the ability of cells to interact with and respond to invading pathogens, and the integration of components of the immune system has contributed to an appreciation of clinical observations about the role the spleen plays in normal biology. The intersection of hematopoiesis, recycling of aging cells, and iron metabolism is most clearly demonstrated in the spleen.

Although not necessary to life under baseline circumstances, the contribution of the spleen to homeostasis under stress is considerable. Ongoing efforts to preserve and manage splenic function will continue to benefit from enhanced appreciation of the underlying biology.

CHAPTER 163

HEMATOLOGY IN AGING

Andrew S. Artz and William B. Ershler

Although most classifications consider patients "older" once the age exceeds 65 or 70 years, age-related changes are not discrete and certainly do not occur at any specific age. A central tenet of gerontology (the study of normal aging) is that biologic measures show increased variation with advancing age, but that these variations are of insufficient magnitude to result in disease per se. Hematologic conditions in older adults have unique features and frequently require a modified approach relative to younger adults. We will focus on anemia in older adults, because this is the most frequent clinically defined hematologic problem among older adults.

EPIDEMIOLOGY

Aging

The median life expectancy continues to rise throughout the world. In the United States, the Centers for Disease Control and Prevention estimates life expectancy at 77.9 years for children born in 2007. For those who survive to age 75 years in this cohort, they may expect to live until 86 years of age (www.cdc.gov/nchs/data/hus/hus10.pdf#022). Therefore the proportion and absolute number of older adults is increasing, and the life expectancy of adults who have reached an advanced age may be considerable. Accordingly we advocate estimating life expectancy for older adults found to have hematologic conditions, and several calculators are available online for this purpose (e.g., http://gosset.wharton.upenn.edu/mortality/perl/CalcForm.html).

Anemia Definition

Historically criteria for diagnosing anemia in older and younger adults applied the World Health Organization (WHO) hemoglobin (Hb) threshold below 13 g/dL for men and less than 12 g/dL for women.[1] Because it was widely recognized that the criteria required modification, Beutler and Waalen[2] evaluated two large databases (the third U.S. National Health and Nutrition Examination Survey [NHANES] and the Scripps-Kaiser database) to develop population-based thresholds, defining the fifth percentile as the lower limit of normal as shown in Table 163-1. Importantly, they excluded patients with low iron stores, vitamin deficiencies, elevated creatinine level of 1.4 mg/dL, and increased markers of inflammation. Therefore the remaining adults were mostly devoid of anemia-related conditions, and actual population prevalence would be higher.

Anemia Prevalence

Most reports of anemia prevalence use the historical WHO thresholds of less than 13 g/dL of Hb for men and less than 12 g/dL for women. For adults 65 years and older residing in the community, the prevalence of anemia is around 10% to 11% and rises with advancing age to around 20% to 25% for those 85 years and older.[3,4] As expected, older adults admitted to the hospital or chronically residing in a nursing-home have lower Hb values and a higher prevalence of anemia.[5]

Race/ethnicity also influences anemia prevalence. Studies from Europe and Japan[3,6] indicate a fairly similar anemia prevalence in older adults. Blacks have lower median Hb values and almost three times higher prevalence of anemia by WHO cutoff points.[4] In a substantial portion of blacks with lower Hb levels α-thalassemia trait with one or two deletions is likely a contributory factor.

Neutropenia and Thrombocytopenia

The incidence of thrombocytopenia, defined as a platelet count below 150×10^9/L, does not appreciably change with age with an average reduction of 19×10^9/L in those 70 to 90 years of age.[7,8] A study of Sardinian villages revealed an increasing incidence of thrombocytopenia with aging, approaching 6% in the seventh decade and 8% for octogenarians.[9] Interestingly, neutropenia (less than 1.5×10^9/L) appears less common with advancing age, such that the prevalence in community-dwelling older adults 75 years and older has been approximated at 0.5%.[10] This does not account for the higher incidence of cytopenias among patients undergoing myelosuppressive challenges such as drugs or infection.

PATHOBIOLOGY

Hematopoietic Changes With Aging

The study of older adults illustrates an overriding paradox that although aging alone does not cause clinically significant cytopenias, aging predisposes to reduced hematopoietic reserve and to diseases, both of which increase the tendency to encounter significantly lower counts in older adults. Major hematopoietic changes occurring with aging are listed in Table 163-2.

The attention to the hematopoietic system must be understood in the context that organ systems are integrated to maintain homeostasis. For example, decreased bone mass and heightened systemic inflammation may adversely influence hematopoiesis.[11,12] Functional decline and the development of frailty with aging relates to a global loss of reserve. Whether hematopoietic perturbations are linked to global decline or the factors promoting functional decline attenuate marrow function cannot be easily deciphered. Reduced neutrophil responses to granulocyte colony-stimulating factors have long been appreciated as predisposing to infection with advancing age, but this occurs in the setting of decline in immune function with aging.[13,14] Further, the prevalence of anemia exceeds 50% in frail older adult patients, and poor functional status or functional limitations predict hematologic toxicities after chemotherapy.

Anemia as a Model of Aging

Anemia may be an ideal model for the interaction of the influence of hematopoietic aging and organ disease. Although anemia is not a normal finding in older adults, the prevalence increases markedly from the seventh decade to the ninth decade of life.[4] For the majority, anemia is related to an underlying cause such as iron deficiency/

Table 163-1 Anemia Definitions*

Group	Hemoglobin (g/dL)
MEN, 60 YEARS OR OLDER

Development of unexplained anemia[4]

G-CSF, Granulocyte colony-stimulating factor.

bleeding, chronic disease/inflammation, or renal insufficiency.[4] An intensive hematologic evaluation of anemia in older adults reveals a wider range of causes than previously appreciated, including 5% to 10% with hematologic neoplasms.[15,16] Nevertheless 30% to 40% of anemic adults lack a discernible cause despite a thorough investigation, and this has become commonly termed *unexplained anemia in the elderly* (Fig. 163-1). Renal insufficiency, hypogonadism, or undiagnosed myelodysplastic syndromes do not seem to account for most cases.[15,17,18] Our recommended approach for anemia in older adults differs from that for younger adults (see box on Evaluating Anemia in Older Adults).

Leukopenia and Thrombocytopenia

The causes of thrombocytopenia and neutropenia, as with anemia, are vast. Although the causes of cytopenias are not unique to older adults, the possibility of more than one cause should not be overlooked. For example, a patient with an emerging bone marrow failure syndrome may be prone to develop severe pancytopenia at the time of a serious infection or other insult.

CLINICAL MANIFESTATIONS

In the industrialized countries, the detection of cytopenias is often encountered after routine laboratory testing or accompanies minor or nonspecific symptoms. Especially for anemia, one may not be able to disentangle anemia symptoms from other conditions that coexist or underlie the anemia (e.g., rheumatoid arthritis). Although fatigue may be the most obvious symptom of anemia, the potential signs and symptoms are protean. Patients frequently attribute fatigue to "growing old." Observational studies demonstrate a clear association between mild hemoglobin reduction (e.g., less than 14 g/dL for women and less than 15 g/dL for men) and reduced quality of life, strength, and mobility.[19-21] Signs and symptoms may also direct one toward a cause, such as a pica suggesting iron deficiency or weight loss directing the clinician toward a systemic illness.

Specific hemoglobin thresholds do not permit one to validate symptoms because patients have different levels of reserve and organ function, pace of hemoglobin fall, and underlying cause for the

Evaluating Anemia in Older Adults

Anemia in older adults is a common finding and frequently results in a request for hematology consultation.

To define anemia, we follow the hemoglobin criteria defined by Beutler and Waalen in Table 163-1. However, hemoglobin trajectory over time is as important. Based on the fact that the average hemoglobin level declines in older adults about 1 g/dL over 15 years or more, we consider decline of 1 g/dL in less than 5 years or 2 g/dL over 10 years significant and supports a complete evaluation. We work diligently to retrieve remote blood counts. Older adults frequently have had blood counts obtained either routinely in the past, before a procedure, or at the time of hospital admission. Counts at the time of hospital admission may be the least reliable because they occur in the context of an illness.

To elicit symptoms, both the patient and family members or caregivers who know the patient are asked about functional changes (walking, naps, activity level) over the short-term (weeks) and longer term (months to years). Many older adults will often attribute functional changes to "old age."

Our basic evaluation begins with a complete blood count, red cell indices, and review of the peripheral smear. The red cell size by mean corpuscular volume is helpful but imperfect. We also perform a reticulocyte count, but 95% or more of anemias in older adults are hypoproliferative. Because anemia can be mixed or multifactorial, we routinely perform the same panel on most patients: serum ferritin, serum iron, total iron-binding capacity, serum creatinine (and estimated renal function), vitamin B_{12}, and thyrotropin levels. We also have found c-reactive protein and serum erythropoietin to be very useful. High c-reactive protein level, such as above 10 mg/L, is frequently associated with inflammatory illnesses and raises caution in interpreting the serum ferritin level. Serum erythropoietin levels are typically in the reference range (i.e., inappropriately low) for most older anemic adults except for iron deficiency, hematologic malignancy, or hyperproductive anemias. Folate levels are rarely low, at least in the United States, where dietary folate supplementation is universal. The remainder of the laboratory tests will be performed as indicated. We do not routinely evaluate for a serum monoclonal gammopathy unless unexplained renal dysfunction, elevated total protein level, elevated calcium level, or bone pain is present.

A ferritin level of less than 50 ng/mL will prompt a complete evaluation for iron deficiency. At a minimum, we embark on an oral iron trial and fecal tests for blood. The lower the iron stores and more evidence for iron deficiency anemia, the more we recommend endoscopic gastrointestinal evaluation, assuming no other cause is clearly established. Other measures exist for diagnosing iron deficiency, such as reticulocyte counts, serum transferrin receptor, or intravenous iron trials. We also empirically treat if vitamin B_{12} levels are less than 200 pg/mL with oral vitamin B_{12} at 1000 mcg for 8 to 12 weeks. If there is no response, we discontinue therapy.

A bone marrow examination is recommended if any of the following are present: unexplained requirement for red blood cell transfusion therapy, unexplained mean corpuscular volume of 97 fL or greater, thrombocytopenia below 120×10^9/L, neutropenia below 1000×10^9/L, or suspicious peripheral smear. If the bone marrow is nondiagnostic, we only repeat the marrow examination at the time of clinical progression (e.g., red blood cell transfusion required, the development of more significant cytopenias).

When the anemia has no established cause, the hemoglobin level is above 10 g/dL, the patient lacks major symptoms, and the hemoglobin kinetics are stable (i.e., fall of less than 1 g/dL over 5 years), we follow up with blood cell counts every 6 months and then annually. Any significant fall in hemoglobin will prompt repeat evaluation. We do not routinely administer erythropoiesis-stimulating agents for unexplained anemia.

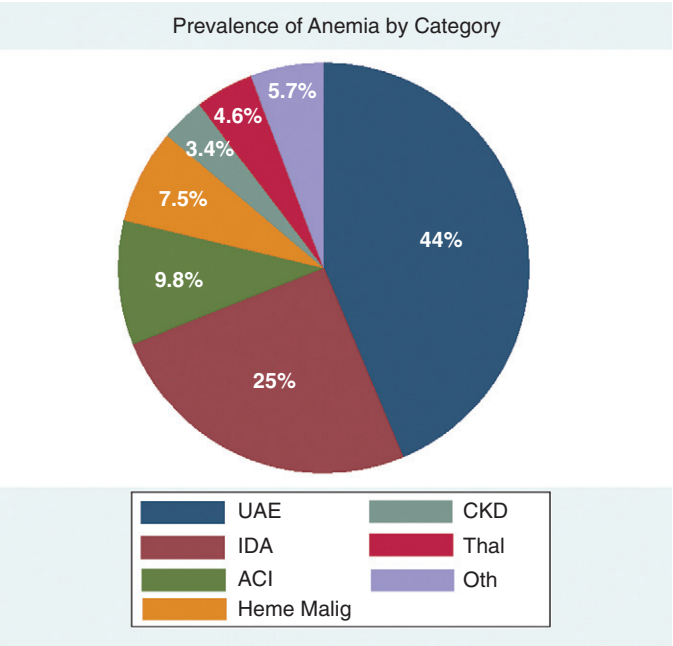

Figure 163-1 CATEGORIZATION OF PRIMARY ANEMIA ETIOLOGY OR UNEXPLAINED ANEMIA IN THE ELDERLY (UAE) IS SHOWN. *IDA,* Iron deficiency anemia; *ACI,* anemia of chronic inflammation; *Heme malig,* hematologic malignancy; *CKD,* chronic kidney disease; *Thal,* thalassemia trait; *Oth,* other. (Other includes hemolysis, 4; alcohol, 3; hypothyroidism, 1; vitamin B_{12} deficiency, 1; medication, 1.) *(From Artz AS, Thirman MF: Unexplained anemia predominates despite an intensive evaluation in a racially diverse cohort of older adults from a referral anemia clinic.* J Gerontol A Biol Sci Med Sci *66:925, 2011.)*

anemia. A more rapid pace of hemoglobin decline is at least as important in provoking symptoms relative to anemia severity. Overall functional reserve and organ function also determines compensation for the stress of anemia. In contrast, a chronic stable anemia, even if severe, may be well compensated. Moreover, patients may adjust their activity level and be unaware of limitations.

Neutropenia and Thrombocytopenia

Because of immune alterations with aging, one expects older adults at a given degree of neutropenia to suffer more infections and/or more serious infections. For example, not only do older adults have a greater probability of developing neutropenia, they also have a heightened risk for life-threatening complications.[22] Thrombocytopenia in older adults increases bleeding risks compared with younger adults, best illustrated in chronic autoimmune thrombocytopenic purpura.[23,24]

LABORATORY MANIFESTATIONS

Diagnosis

The use of age-adjusted norms remains quite controversial because normal aging itself has only a small impact on normal values. For cytopenias, blood counts are mandatory for diagnosis, to establish severity, and to guide the etiologic evaluation. For anemia, we advocate applying the hemoglobin thresholds published by Beutler and Waalen as seen in Table 163-1. Thresholds to define neutropenia and thrombocytopenia should not differ from younger adults.

Laboratory Evaluation for Anemia

To the extent significant cytopenias are uncommon among community-dwelling adults and the decline with normal aging is modest, a cause should always be sought and will often be found. Remote blood counts are of enormous value, not only to ensure the acquired nature, but to assess the tempo of change over time. Most older adults in industrialized countries will have prior blood counts. An evaluation of worsening neutropenia or thrombocytopenia, similar to anemia, will typically yield a cause. Review of the blood smear can be enormously useful, if not simply to exclude a high-risk hematologic disorder (e.g., lack of peripheral blood blasts and significant dysplasia or cytosis).

Table 163-3 Differential Diagnosis for Common Causes of Cytopenias in Older Adults

Cytopenia of one or more lineages
Hematologic neoplasm
Vitamin B_{12} deficiency
Autoimmune disorder
Consumptive coagulopathy
Systemic inflammation
Alcohol
Splenomegaly
Thyroid dysfunction
Human immunodeficiency virus

Bone Marrow Evaluation

Although a bone marrow examination may be invaluable in excluding serious marrow-related conditions, all cytopenias in older adults do not warrant a bone marrow examination. We favor delaying bone marrow examination until recovery from acute events unless a high-grade hematologic malignancy that would warrant immediate treatment is suspected. Mild fluctuations of counts, particularly within the range found over years, without other evidence of a hematologic malignancy may allow one to safely defer a bone marrow examination.

DIFFERENTIAL DIAGNOSIS

It is important to distinguish true and clinically important findings from false or transiently low values by having serial blood counts and/or a review of the peripheral smear.

In addition to causes delineated in Table 163-3, other causes specific for anemia in older adults include unexplained iron deficiency/blood loss, folate deficiency, hemolysis, and androgen deprivation.

PROGNOSIS

The underlying condition driving the hematologic abnormality usually dictates prognosis. There is now a wealth of data that suggests that even a mildly low hemoglobin concentration is an independent adverse prognostic factor in older adult patients. It is likely anemia, rather than an obscure or unrecognized condition, imparts an adverse prognosis because a serious underlying condition is typically not found in patients with isolated mild anemia. A lower hemoglobin concentration independently increases the risks for hospitalization and mortality, even in those 85 years and older.[20,21,25-29]

THERAPY

To the extent possible, the underlying illness should be treated. Particularly for anemia, the cause often remains obscure or the underlying illness may not be amenable to therapy. We favor diagnostic and therapeutic trials of iron or vitamins but for a defined period of 3 months and discontinuing if ineffective. One must be attuned to

Assessment of Older Adults With Hematologic Malignancies

Optimal treatment for a hematologic condition in an older patient must be measured in terms of both efficacy and anticipated toxicity. Assessing patients' reserve before treatment not only promotes tailoring treatment, but also provides an objective baseline assessment and an opportunity to direct interventions for these limitations.

For all adults over 50 years, we screen for age-associated vulnerabilities. Cataloging comorbid conditions and assessing performance status (PS) play a central role. Estimating PS alone provides only a crude estimate of tolerance to treatment. An Eastern Cooperative Oncology Group (ECOG) PS of 2 or more suggests important health limitations, but one must recognize that a PS of 0 to 1 covers a broad range of health, from robust to substantial limitations. In older patients, it is important to estimate PS before the current illness, because this is more likely to provide insight into vulnerability. We find insufficient data to recommend a specific comorbidity tool or index. However, certain tools such as the Charlson comorbidity index or hematopoietic cell transplantation–comorbidity index have been validated in the context of certain diseases and their treatments and thus may be invaluable in specific situations.

The PS and comorbidity index should be complemented by screening for other vulnerabilities, particularly in those older patients with a PS of 0 to 2 for whom intensive therapy is under consideration. Limitations in the following domains also suggest vulnerability:

- Instrumental activities of daily living, which are the skills required to live independently in the community (e.g., transportation, paying bills, shopping)
- Poor caregiver support
- Cognition
- Age 70 years and older

One should not overlook inquiring specifically about whether patients perceive problems for the recommended treatment. Patients will often relay difficulties not recognized by a standard medical examination (e.g., caring for an ill-spouse, limited prescription coverage, and poor perceived health). More formal screening instruments are available and useful if familiarity can be achieved (e.g., Vulnerable Elders Survey-13).

Knowledge of disease-based response rates will allow further individualizing treatment decisions. Responses to imatinib for chronic-phase chronic myeloid leukemia do not differ substantially by age, whereas acute myeloid leukemia induction results in lower responses, shorter disease-free survival, and greater toxicity relative to younger adults, even among relatively "young" healthy adults in their seventh decade of life.

Although disease-based therapy exists on a spectrum, we generally divide therapy into low-intensity, intermediate-intensity, or high-intensity therapy. High-intensity treatment entails strategies such as AML induction and autologous or allogeneic hematopoietic cell transplantation, and these have high rates of early death for patients with health limitations. Prior treatment and disease status influence the expected complication rate. Refractory or relapsed disease or multiple prior regimens may escalate the expected complications and may warrant providing traditionally less-intensive therapy instead of high-intensity treatment strategies. We typically reserve high-intensity therapy for patients with a preserved PS. We recommend that a patient with any vulnerability on screening undergo a more comprehensive geriatric assessment, if available, before curative-intent intensive therapy. Clinics focusing on issues and research in geriatric oncology are becoming available, and identifying experts (physician and nonphysician) in aging with an interest in oncology is invaluable. They often can connect patients with resources for specific problems (e.g., home care, transportation, financial help, assisted living).

Intermediate-intensity therapy such as CHOP (cyclophosphamide, hydroxydaunomycin, vincristine [Oncovin], and prednisone)-like regimens and fludarabine plus cyclophosphamide may be somewhat more likely to produce manageable toxicity-related morbidity in older patients, but they remain efficacious and can be administered safely to those with a PS of 2 or better. Demethylating agents span the gap between low- and intermediate-intensity therapy. Low-intensity therapies, such as imatinib or supportive care alone, generally require only a reasonable nondisease life expectancy of more than a couple of months and can be given with an ECOG PS of 3 or less.

Patient support often extends past the traditional nuclear family and may include friends, business associates, or extended relatives. We strongly encourage a family meeting before initiating treatment at which goals and expectations are clearly discussed. Not only will insights be gained into the available support system, but communicating to the entire team harmonizes goals for providers and patients alike. Supportive care should be addressed prospectively before treatment plans and with the entire "treatment family." Standard guidelines for infectious disease prophylaxis and growth factor support should be supplemented with plans to address limitations found in the initial assessment.

fluctuations, normal variation, or confounding factors in assessing response. For example, anemia detected immediately after a hospitalization may reflect phlebotomy, dilution, and an acute inflammatory response. The anemia may improve slowly after hospitalization even without therapy.

For unexplained or idiopathic cytopenias, caution should be exercised in employing erythropoiesis-stimulating agents because of concerns for toxicity. Although not clearly established, it is unlikely that toxicity to these agents would be less in older patients. The data are sparse for erythropoiesis-stimulating agents and unexplained anemia in older adults.[30,31] More importantly, erythropoiesis-stimulating agent treatment for anemia associated with renal insufficiency not requiring dialysis has been associated with neutral to negative results.[32,33]

Polypharmacy remains a frequent problem in older adults and may either cause hematologic abnormalities or adversely interact with the detected blood abnormality. The primary physician, once prompted, may determine many medications are unnecessary and can simply be discontinued.

For older adults with an established hematologic malignancy for which aggressive therapy may be entertained, a detailed assessment may guide decision making (see box on Assessment of Older Adults With Hematologic Malignancies).

FUTURE DIRECTIONS

The availability of large databases that contain representative populations or sometimes primarily older populations (e.g., U.S. Medicare program) represents a tremendous opportunity for intensive study in older adults. Studies of normal healthy aging individuals are of tremendous value. Although interventional trials among older persons remain challenging, the growing number of older and often relatively healthy adults mandates efforts to study older adults to inform clinical practice.

RESOURCES FOR THE HEMATOLOGIST: INTERPRETIVE COMMENTS AND SELECTED REFERENCE VALUES FOR NEONATAL, PEDIATRIC, AND ADULT POPULATIONS

Andrea M. Sheehan and Donald L. Yee*

APPENDIX CONTENTS

RED BLOOD CELL TESTING
- Estimated Blood Volumes (Plasma Volume and Red Blood Cell Mass)
- Complete Blood Count (Red Blood Cell) Parameters
- Red Blood Cell Distribution Width
- Reticulocyte Count (Absolute And Percentage)
- Immature Reticulocyte Fraction
- Reticulocyte Hemoglobin Equivalent
- Haptoglobin
- Hemoglobin F and Hemoglobin A_2
- Sickle Cell Screen (Hemoglobin S Solubility Test)
- Ferritin
- Total Iron-Binding Capacity, Transferrin Saturation
- Iron
- Erythropoietin
- Folate (RBC or Serum/Plasma)
- Vitamin B_{12} (Cobalamin)
- Homocysteine
- Methylmalonic Acid
- Osmotic Fragility
- Red Blood Cell Enzyme Activity in Adults and Term Infants
- Red Cell Glycolytic Intermediate Metabolites in Normal Adults, Term Infants, and Premature Infants

WHITE BLOOD CELL AND IMMUNOLOGIC TESTING
- Leukocyte Counts (Absolute and Percentage)
- Lymphocyte Subsets
- Immunoglobulin A
- Immunoglobulin E
- Immunoglobulin G
- Immunoglobulin G Subclasses
- Immunoglobulin M
- Immunoglobulin Light Chains
- Complement Fractions C3 and C4

PLATELET AND COAGULATION TESTING
- Platelet Count and Mean Platelet Volume
- Immature Platelet Fraction
- Coagulation Screening Tests (PT, aPTT, Fibrinogen)
- Coagulation Factor Levels (Fibrinogen, II, V, VII, VIII, von Willebrand Factor, IX, X, XI, Contact Pathway Factors)
- Natural Anticoagulants (Antithrombin, Protein C, Protein S, Tissue Factor Pathway Inhibitor)
- D-dimer
- PFA-100

This appendix is intended to provide useful supplemental information to clinicians in selecting, obtaining, and interpreting certain key laboratory tests relevant to hematology. The most appropriate reference range for a particular test is dependent on the specific testing methods employed (including reagents and instrumentation), patient age and gender, testing conditions, preanalytical variables, and other concurrent medical conditions. The listed reference ranges thus provide only a rough guide to differentiating normal from abnormal results. Clinicians are encouraged to seek out the most applicable and appropriate reference range for a particular test, preferably using reference data that are specific to the performing laboratory and the patient population being tested. Although the tables listed herein provide some age-specific information, caution is particularly emphasized in interpreting results obtained from testing infants and children.

Estimated Blood Volumes (Includes Plasma Volume, Red Blood Cell Mass)

The red cell volume, plasma volume, and total blood volume are calculated from hematocrit (packed cell volume) and isotope dilution after reinjection of red cells labeled with a radioactive isotope. Performance of a red cell mass determination is occasionally indicated in the investigation of polycythemia to differentiate primary or secondary polycythemia (elevated red cell mass) from relative polycythemia (normal red cell mass). Table 164-1 provides typical reference ranges.

Total blood volume can also be estimated by calculation†:

$$\text{Total Blood Volume for Males} = [0.3669 \times (\text{Height in Meters})^3] + [0.03219 \times (\text{Weight in Kilograms})] + 0.6041;$$

$$\text{Total Blood Volume for Females} = [0.3561 \times (\text{Height in Meters})^3] + [0.03308 \times (\text{Weight in Kilograms})] + 0.1833.$$

*Previously collated by Donald L. Yee, Catherine M. Bollard, and Sharon M. Geaghan.

†From Nadler SB, Hidalgo JU, Bloch T: Prediction of blood volume in normal human adults, *Surgery* 51:224, 1962.

INTERPRETIVE COMMENTS

Complete Blood Count (Red Blood Cell) Parameters

Summary points	• Used to identify anemia or polycythemia (RBC count, hemoglobin, hematocrit) • RBC indices (MCV, MCH, MCHC, RDW) can characterize anemia according to RBC size and degrees of hemoglobinization and anisopoikilocytosis
Methodology	Automated hematology analyzer—flow cytometric or impedance methods
Specimen requirements	Whole blood: EDTA
Indications	Evaluation of anemia or polycythemia
Reference range	Table 164-2
Interpretation	• Anemia (low hemoglobin, hematocrit, RBC count) • Microcytic, hypochromic: iron deficiency (often with high RDW), thalassemia (typically normal RDW but can be high, high RBC count), sideroblastic anemia (may be dimorphic RBCs on peripheral smear), some cases of anemia of chronic disease • Normocytic, normochromic: aplastic anemia, anemia of chronic disease, renal disease, hemolysis, bone marrow infiltration, drugs, lead poisoning, myelodysplastic syndrome • Macrocytic: vitamin B_{12} or folate deficiency, liver disease, antimetabolite drugs, bone marrow failure, myelodysplastic syndrome, hemolysis with high reticulocyte count, hypothyroidism • Polycythemia (high hemoglobin, hematocrit) • Primary: polycythemia vera, altered erythropoietin receptor • Secondary: pulmonary disease, high-affinity hemoglobin, tumor-related
Related tests	• Peripheral smear review, reticulocyte count, bone marrow aspiration/biopsy, tests of renal and hepatic function, hemoglobin fractionation/electrophoresis • Microcytic, hypochromic anemias: iron studies, lead level (children, hemoglobin fractionation/electrophoresis) • Macrocytic anemias: vitamin B_{12}, folate, homocysteine, methylmalonic acid • Normocytic anemias: markers of hemolysis • Polycythemia: family history, JAK2 mutation testing, erythropoietin level
Interfering substances	Clotted or hemolyzed sample, cold agglutinin, lipemia, marked turbidity

EDTA, Ethylenediaminetetraacetic acid; *MCH,* mean corpuscular hemoglobin; *MCHC,* mean corpuscular hemoglobin concentration; *MCV,* mean corpuscular volume; *RBC,* red blood cell; *RDW,* red blood cell distribution width.

Red Blood Cell Distribution Width

Summary points	• Measures variability of red blood cell size (anisocytosis) • Reported as either CV, SD, or both
Methodology	Automated hematology analyzer
Specimen requirements	Whole blood: EDTA
Indications	Evaluation of anemia
Reference range	RDW-CV: 11%-15% (based on adults)*
Interpretation	• Elevated with increased variability in red blood cell size and shape; normal with more uniform, red blood cell size • Hypochromic microcytic anemia • Usually elevated with iron deficiency, hereditary sideroblastic anemia, thalassemia intermedia and major, and red blood cell fragmentation • Normal with anemia of chronic disease and thalassemia minor • Normocytic or macrocytic anemia • Usually elevated in folate or vitamin B_{12} deficiency, mixed iron and folate or vitamin B_{12} deficiency, some hemoglobinopathies, myelofibrosis, acquired sideroblastic anemia, immune hemolytic anemia, and cold agglutinins • Usually normal in anemia of chronic disease, some hemoglobinopathies, hemorrhage, hereditary spherocytosis, and bone marrow failure • RDW-CV = (SD of red cell volume/MCV)(100) reported more commonly than the RDW-SD • RDW-SD less influenced by MCV and may be more accurate assessment of variability in red blood cell size • Reference range will vary with the instrument used—check with laboratory
Related tests	RBC, Hb, Hct, MCV, MCH, MCHC, peripheral blood smear
Interfering substances	Hemolyzed or clotted specimen
References	Briggs C: Quality counts: New parameters in blood cell counting, *Int J Lab Hematol* 31:277, 2009. *Evans TC, Jehle D: The red blood cell distribution width, *J Emerg Med* 9:71, 1991.

CV, Coefficient of variation; *EDTA,* ethylenediaminetetraacetic acid; *Hb,* hemoglobin; *Hct,* hematocrit; *MCH,* mean corpuscular hemoglobin; *MCHC,* mean corpuscular hemoglobin concentration; *MCV,* mean corpuscular volume; *RBC,* red blood cell count; *RDW,* red blood cell distribution width; *SD,* standard deviation.

Reticulocyte Count (Absolute and Percentage)

Summary points	• Used to assess erythroid production • In setting of anemia, can aid in distinguishing between destructive process (hemolysis) and marrow production problem
Methodology	Automated hematology analyzer, flow cytometry
Specimen requirements	Whole blood: EDTA
Indications	Differential diagnosis of anemia (destruction versus marrow production problem); evaluate marrow response to anemia; monitor response to therapy (treatment of nutritional anemias, post immunosuppressive therapy for aplastic anemia, growth factors, post chemotherapy, or bone marrow transplant)
Reference range	Table 164-3
Interpretation	• Elevated with marrow response to anemia, implying decreased RBC life span, marrow recovery, or response to treatment • Decreased (or inadequately elevated) in nutritional anemias, marrow suppression (infections, toxic exposures, malignancy), marrow failure • Corrected reticulocyte count (absolute reticulocyte count/reticulocyte maturation time) and RPI [reticulocyte percentage × (hematocrit/45) × (1/reticulocyte maturation time)] adjust for the degree of anemia and account for reticulocyte maturation time in assessing appropriateness of the marrow response
Related tests	Complete blood count, reticulocyte hemoglobin, immature reticulocyte fraction, mean reticulocyte volume, corrected reticulocyte count, RPI, direct antiglobulin test, markers of hemolysis
Interfering substances	Clotted or hemolyzed sample

EDTA, Ethylenediaminetetraacetic acid; *RBC,* red blood cell; *RPI,* reticulocyte production index.

Immature Reticulocyte Fraction

Summary points	• Indicator of marrow response to anemia • May be useful to follow engraftment after bone marrow transplant
Methodology	Automated hematology analyzer—flow cytometric method
Specimen requirements	Whole blood: EDTA
Indications	Suspected anemia, differential diagnosis of anemia, assess marrow response to anemia, after injury, chemotherapy, growth factor treatment, or bone marrow transplant
Reference range	Table 164-4
Interpretation	• Decreased in marrow failure states, increased with marrow response to anemia • Increased levels after bone marrow transplant appear to correlate with engraftment and precede other cell counts
Related tests	Complete blood count, reticulocyte count, reticulocyte hemoglobin, mean corpuscular volume reticulocyte
Interfering substances	Clotted or hemolyzed sample
Reference	Piva E, Brugnara C, Chiandetti L, et al: Automated reticulocyte counting: State of the art and clinical applications in the evaluation of erythropoiesis, *Clin Chem Lab Med* 48:1369, 2010.

EDTA, Ethylenediaminetetraacetic acid.

Reticulocyte Hemoglobin Equivalent

Summary points	• May be useful in early detection of iron deficiency • CHr is a similar but not identical parameter; whether Ret-He or CHr is reported depends on the hematology analyzer used
Methodology	Automated hematology analyzer—flow cytometric method
Specimen requirements	Whole blood: EDTA
Indications	Suspected anemia, assessment of iron status, differential diagnosis of anemia, assess response to growth factor therapy
Reference range	Table 164-5
Interpretation	• Decreased in iron deficiency and may be decreased in thalassemia • Decreased levels in renal failure may suggest functional iron deficiency
Related tests	Complete blood count, reticulocyte count, immature reticulocyte fraction, mean corpuscular volume reticulocyte, iron studies
Interfering substances	Hemolyzed or clotted specimen
Reference	Piva E, Brugnara C, Chiandetti L, et al: Automated reticulocyte counting: State of the art and clinical applications in the evaluation of erythropoiesis, *Clin Chem Lab Med* 48:1369, 2010.

CHr, Reticulocyte hemoglobin content; *EDTA,* ethylenediaminetetraacetic acid; *Ret-He,* reticulocyte hemoglobin equivalent.

Haptoglobin

Summary points	• Binds free hemoglobin in plasma • Haptoglobin-hemoglobin complex removed by reticuloendothelial system • Often used to evaluate for intravascular hemolysis but has low sensitivity and specificity • Acute phase reactant
Methodology	Immunoassay
Specimen requirements	Lithium heparin, EDTA, or plain tube
Indications	Evaluation of hemolysis, especially intravascular
Reference range	Table 164-6
Interpretation	• Levels low in neonates and young infants, severe extravascular hemolysis, liver disease, massive tissue hemorrhage, and congenital deficiency states • High levels occur with pregnancy, steroids, estrogen, and acute phase responses. Preexisting high levels may mask hemolysis
Related tests	Plasma free hemoglobin concentration, LDH, bilirubin, reticulocyte count
Interfering substances	Lipemia
Reference	Owen JA, Better FC, Hoban J: A simple method for the determination of serum haptoglobins, *J Clin Pathol* 13:163, 1960.

EDTA, Ethylenediaminetetraacetic acid; *LDH,* lactate dehydrogenase.

Hemoglobin F and Hemoglobin A_2

Summary points	• Hemoglobin F composed of two α and two γ chains—the dominant hemoglobin during gestation and early infancy • Hemoglobin A_2 composed of two α and two δ chains—a normal minor hemoglobin in adulthood • Hemoglobin A_2 present at very low levels at birth, gradually increasing to adult levels over the first 1 to 2 years of life
Methodology	Gel electrophoresis or high-performance liquid chromatography
Specimen requirements	Whole blood: EDTA
Indications	Assess for β-thalassemia (including trait) or other hemoglobin disorder; evaluate for bone marrow failure syndromes or juvenile myelomonocytic leukemia (elevated hemoglobin F); evaluate patients being treated with hydroxyurea for hemoglobin F response (e.g., sickle cell anemia)
Reference range	Tables 164-7 and 164-8
Interpretation	• Hemoglobin F elevated in β-thalassemia, $\delta\beta$-thalassemia, hereditary persistence of fetal hemoglobin, sickle cell anemia, other hemoglobin disorders, some bone marrow failure syndromes, and juvenile myelomonocytic leukemia • Hemoglobin A_2 elevated in β-thalassemia, unstable β-chain variants, megaloblastic anemia, thyrotoxicosis, decreased in $\delta\beta$-thalassemia and at times in iron deficiency, lead poisoning, anemia of chronic disease, sideroblastic anemia, and hypothyroidism • Infants with suspected β-thalassemia disorders may require repeat testing at 6 months to 1 year of age to reliably evaluate hemoglobin A_2 levels
Related tests	Complete blood count, peripheral smear review, molecular diagnostic testing for β-chain mutations

EDTA, Ethylenediaminetetraacetic acid.

Sickle Cell Screen (Hemoglobin S Solubility Test)

Summary points	• Rapid test to evaluate for the presence of hemoglobin S >20% • Also known as a *sickle prep* or by the brand name of a commonly used test kit—*Sickledex*
Methodology	Differential solubility
Specimen requirements	Whole blood: EDTA, some laboratories accept heparin or ACD anticoagulants
Indications	Suspected hemoglobin S disorder
Reference range	Negative
Interpretation	• Positive when hemoglobin S >30%, negative when hemoglobin S <20% • Hemoglobin S between 20% and 30% may be positive or negative • False positive with cryoglobulinemia, multiple myeloma, dysglobulinemia, certain rare hemoglobinopathies (C Harlem or C Georgetown); false negative with severe anemia, high hemoglobin F, infants under 6 months • Recent transfusion may give false-positive or false-negative results • Does not distinguish between sickle cell trait and sickle cell disease or compound heterozygotes for hemoglobin S and another hemoglobinopathy • Positive results should be confirmed by another method
Related tests	Hemoglobin fractionation/electrophoresis
Interfering substances	Hemolyzed sample
References	Lange RD, Minnich V, Moore CV: Effect of oxygen tension and of pH on the sickling and mechanical fragility of erythrocytes from patients with sickle cell anemia and sickle cell trait, *J Lab Clin Med* 37:789, 1951. ACD, Acid citrate dextrose; *EDTA,* Ethylenediaminetetraacetic acid.

Ferritin

Summary points	• Ferritin concentration reflects body iron stores; decreased in iron deficiency, increased in iron overload • Useful in distinguishing between iron deficiency anemia and anemia of chronic disease, thalassemia minor • Assessment of iron deficiency may be confounded by infection, inflammation, malignancy, and liver disease, all of which raise ferritin concentration • More sensitive and reliable than serum iron, transferrin (total iron-binding capacity), and transferrin saturation for detecting iron deficiency
Methodology	Immunoassay
Specimen requirements	Lithium heparin or plain tube
Indications	Assess suspected iron deficiency or iron overload
Reference range	Table 164-9
Interpretation	• Levels are age and gender dependent. Levels in adult females are generally lower than in adult males, but following menopause progressively approach those of males • Levels elevated with iron overload, Gaucher disease, acute hepatitis, malignancies, hemophagocytic lymphohistiocytosis
Related tests	Iron, transferrin (total iron-binding capacity), transferrin saturation, soluble transferrin receptor
Interfering substances	Antianimal antigen antibodies

Soluble Transferrin Receptor

Summary points	• Transferrin receptor derived mainly from erythroid marrow cells • Reflects iron status independent of concurrent inflammation
Methodology	Immunoassay
Specimen requirements	Lithium heparin or plain tube
Indications	Assess for iron deficiency, especially in setting of inflammation
Reference range	Table 164-10
Interpretation	• Levels decreased with erythroid hypoplasia states, increased with increased iron demand (erythroid hyperplasia [hemolysis, recent blood loss, thalassemia], iron deficiency) • Unaffected by inflammation or liver disease • African Americans and individuals at high altitude may have slightly higher values
Related tests	Iron, transferrin (total iron-binding capacity), transferrin saturation, ferritin
Interfering substances	Lipemia

Total Iron-Binding Capacity, Transferrin Saturation

Summary points	• Transferrin—the major iron transporter protein in plasma • TIBC—often measured as transferrin concentration, especially in pediatrics, because of smaller specimen volume required for children • One molecule of transferrin can bind two molecules of iron • TIBC and transferrin concentration—typically elevated in iron deficiency due to increased transferrin gene expression • Transferrin saturation—calculated as serum iron concentration divided by the iron-binding capacity; low in iron deficiency, elevated in iron overload
Methodology	Immunoassay and calculation
Specimen requirements	Lithium heparin or plain tube
Indications	Assess suspected iron deficiency, iron overload, and acute iron poisoning (transferrin saturation elevated in the latter)
Reference range	Table 164-11
Interpretation	• Pregnancy and oral contraceptives increase transferrin concentration, leading to low transferrin saturation • Acute phase response can decrease transferrin and TIBC • Spuriously high TIBC can occur with acute hepatitis and after iron dextran injection
Related tests	Iron, ferritin, soluble transferrin receptor
Interfering substances	Lipemia

TIBC, Total iron binding capacity.

Iron

Summary points	• Reflects recent iron ingestion and absorption • Undergoes circadian variation • Less reliable than ferritin for assessing iron deficiency
Methodology	Spectrophotometry
Specimen requirements	Lithium heparin or plain tube
Indications	Assess suspected iron deficiency, iron overload, acute iron poisoning, iron absorption (iron challenge test)
Reference range	Table 164-12
Interpretation	• Acute phase response, malignancy, and ascorbate deficiency can decrease iron concentration, whereas liver disease, ineffective erythropoiesis, and aplastic and sideroblastic anemias can increase it • For oral iron challenge testing, an increase of at least 100 μg/dL 1 to 4 hours after ingestion of 65 mg elemental iron is thought to indicate adequate absorption
Related tests	Ferritin, transferrin (total iron-binding capacity), transferrin saturation, soluble transferrin receptor
Reference	Cook JD: Diagnosis and management of iron-deficiency anaemia, *Best Pract Res Clin Haematol* 18:319, 2005.

Erythropoietin

Summary points	• Glycoprotein hormone secreted mostly by kidney but also liver • Level varies inversely with hematocrit, stimulated by hypoxia • May be secreted by certain tumors, leading to polycythemia • Results obtained with one method may differ significantly from those obtained with another—any serial testing over time should be performed using the same test method
Methodology	Immunoassay
Specimen requirements	Lithium heparin, EDTA, or plain tube
Indications	Can differentiate primary (decreased concentration) from secondary erythrocytosis (elevated), but testing may be problematic given the broad overlap between the two groups. Levels are usually increased in anemia except in chronic renal failure patients, in whom levels may be used to monitor erythropoietin therapy
Reference range	Adult values approximately 3-16 milli–International Unit/mL; Table 164-13
Interpretation	Normal or low levels with primary polycythemia; elevated levels with most forms of secondary polycythemia
Interfering substances	Lipemia
Reference	Cotes PM, Doré CJ, Yin JA, et al: Determination of serum immunoreactive erythropoietin in the investigation of erythrocytosis, *N Engl J Med* 315:283, 1986.

EDTA, Ethylenediaminetetraacetic acid.

Folate (RBC or Serum/Plasma)

Summary points	• Folate—commonly assessed in setting of macrocytic anemia along with vitamin B_{12} (should be done concurrently) • RBC folate less sensitive to short-term dietary changes than serum folate; more reflective of tissue folate stores, more specific for folate deficiency • Folate deficiency usually nutritional in origin or due to inadequate intake for increased demand (pregnancy, hemolytic anemias, liver disease)
Methodology	Immunoassay
Specimen requirements	RBC: whole blood: EDTA; protect from light for RBC Serum: plain or serum separator tube (fasting state preferred)
Indications	Macrocytic or megaloblastic anemia, workup of possible nutritional deficiencies or myelodysplastic syndrome, unexplained neurologic symptoms or dementia
Reference range*	Table 164-14
Interpretation	• Decreased in nutritional deficiencies (pregnancy, alcoholism, older adults), antimetabolite therapy (methotrexate, for example), rarely due to inherited metabolic disorders • May be decreased in vitamin B_{12} (cobalamin) deficiency • Additional testing for pathway intermediates homocysteine and MMA can help distinguish between folate and vitamin B_{12} deficiency in patients who have borderline levels of either • Homocysteine—elevated in both folate and vitamin B_{12} deficiency • MMA—elevated in vitamin B_{12} but not folate deficiency
Related tests	Vitamin B_{12}, homocysteine, MMA, complete blood count
Interfering substances	Excessive light exposure before testing, hemolysis, lipemia
Reference	Kaferle J, Strzoda CE: Evaluation of macrocytosis, *Am Fam Physician* 79:203, 2009.

EDTA, Ethylenediaminetetraacetic acid; *MMA,* methylmalonic acid; *RBC,* red blood cell.

Vitamin B_{12} (Cobalamin)

Summary points	• Commonly assessed in setting of macrocytic anemia along with folate (should be done concurrently to avoid undiagnosed vitamin B_{12} deficiency) • Often due to inadequate gastric absorption (pernicious anemia, gastric bypass) or lack of small bowel reabsorption (malabsorption, Crohn disease, small intestinal surgery) • Nutritional deficiency uncommon but strict vegans are at risk (vitamin B_{12} available only from animal sources); also seen in alcoholics, older adults, malnutrition
Methodology	Immunoassay
Specimen requirements	Plain or serum separator tube
Indications	Macrocytic or megaloblastic anemia, pancytopenia, workup of possible nutritional deficiencies or myelodysplastic syndrome, unexplained neurologic symptoms or dementia, hypersegmented neutrophils on peripheral smear
Reference range	Table 164-15
Interpretation	• Low levels diagnostic of deficiency; pregnancy lowers vitamin B_{12} level • Follow-up testing for low levels to diagnose pernicious anemia: parietal cell antibodies, antiintrinsic factor antibodies • Additional testing for pathway intermediates homocysteine and MMA can help distinguish between folate and vitamin B_{12} deficiency in patients with borderline levels of either • Homocysteine—elevated in both folate and vitamin B_{12} deficiency • MMA—elevated in vitamin B_{12} but not folate deficiency
Related tests	Folate, homocysteine, MMA, complete blood count, parietal cell antibodies, antiintrinsic factor antibodies, serum gastrin
Interfering substances	Excessive light exposure before testing, hemolyzed sample
Reference	Kaferle J, Strzoda CE: Evaluation of macrocytosis, *Am Fam Physician* 79:203, 2009.

MMA, Methylmalonic acid.

Homocysteine

Summary points	• Used in differentiating vitamin B_{12} from folate deficiency, evaluating hereditary metabolic disorders, and assessing cardiovascular risk
Methodology	Liquid chromatography— tandem mass spectrometry, stable isotope dilution analysis, quantitative enzymatic
Specimen requirements	Plain, EDTA, heparin, or serum separator tube (fasting state preferred)
Indications	Suspected B_{12} or folate deficiency with equivocal initial testing (folate, vitamin B_{12} level), disorder of methionine metabolism, assess cardiovascular or prothrombotic risk
Reference range	Table 164-16
Interpretation	• Testing for pathway intermediates homocysteine and MMA can help distinguish between folate and vitamin B_{12} deficiency in patients with borderline levels of either • Homocysteine—elevated in both folate and vitamin B_{12} deficiency • MMA—elevated in vitamin B_{12} but not folate deficiency • Levels decrease with vitamin supplementation • May be elevated due to age, medications, smoking, renal disease, poor nutrition, thyroid disease, MTHFR 677C→T polymorphism • Serum/plasma should be separated quickly from red blood cells to prevent false elevations • Recent consumption of high-protein meal may falsely elevate level
Related tests	Folate, vitamin B_{12}, MMA, complete blood count, methionine, plasma amino acids, urine organic acids
Reference	Refsum H, Smith AD, Ueland PM, et al: Facts and recommendations about total homocysteine determinations: An expert opinion, *Clin Chem* 501:3, 2004.

EDTA, Ethylenediaminetetraacetic acid; *MMA,* methylmalonic acid.

Methylmalonic Acid

Summary points	• Used in differentiating vitamin B_{12} from folate deficiency and evaluating hereditary metabolic disorders
Methodology	Liquid chromatography—tandem mass spectrometry
Specimen requirements	Plain, EDTA, heparin, or serum separator tube; urine levels may also be measured
Indications	Suspected vitamin B_{12} or folate deficiency with equivocal initial testing (folate, vitamin B_{12} level), metabolic disorder (methylmalonic acidemia)
Reference range	Table 164-17
Interpretation	• Testing for pathway intermediates homocysteine and MMA can help distinguish between folate and vitamin B_{12} deficiency in patients with borderline levels of either • Homocysteine—elevated in both folate and vitamin B_{12} deficiency • MMA—elevated in vitamin B_{12} but not folate deficiency • Elevated in vitamin B_{12} deficiency, renal failure, thyroid disease, bacterial overgrowth of small bowel • Markedly elevated levels in a child suggest hereditary metabolic disorder but must be confirmed
Related tests	Folate, vitamin B_{12}, homocysteine, complete blood count
Interfering substances	Hemolyzed sample, lipemia

EDTA, Ethylenediaminetetraacetic acid; *MMA,* methylmalonic acid.

Osmotic Fragility

Summary points	• Used in differential diagnosis of hemolytic anemia • Usually increased osmotic fragility with hereditary spherocytosis • Increased osmotic fragility can be seen in other conditions with increased spherocytes and other hematologic disorders
Methodology	Lysis of erythrocytes in gradient of hyposmolar solutions; degree of hemolysis commonly measured by spectrophotometry
Specimen requirements	Whole blood: EDTA or heparin
Indications	Hemolytic anemia, suspected hereditary spherocytosis
Reference range	Normal curves generated by individual laboratories; patient results are plotted against a normal curve
Interpretation	• Patients with hereditary spherocytosis will show increased lysis of red blood cells in hyposmolar solutions compared with normal controls • Increased osmotic fragility also seen in other causes of spherocytosis (autoimmune hemolytic anemia, post transfusion), other hematologic disorders (pyruvate kinase deficiency, G6PD deficiency, hereditary stomatocytosis, hereditary pyropoikilocytosis), Rh-null phenotype • Decreased osmotic fragility seen in sickle cell disease, thalassemia, iron deficiency • Normal test does not exclude hereditary spherocytosis (the most fragile cells may have already lysed)—repeat testing at time when patient is at baseline state and hematologically stable may be useful as may performing test with incubation overnight (increases sensitivity) • Measurements taken either immediately or after incubation for 24 hours at 37° C enhance assay sensitivity • Results may vary depending on patient age, gender, medication history, and presence or absence of active hemolysis
Related tests	Flow cytometry for band 3 using EMA, peripheral smear, direct antiglobulin test, complete blood count
Interfering substances	Hemolyzed specimen, specimen age may falsely increase background hemolysis (laboratory may require submitting concurrent sample from normal nonrelative to control for this)

EDTA, Ethylenediaminetetraacetic acid; *EMA,* eosin-5′-maleimide; *G6PD,* glucose-6-phosphate dehydrogenase.

Leukocyte Counts (Absolute and Percentage)

Summary points	• Also called *WBC count and differential* • Part of complete blood count
Methodology	Automated hematology analyzer—flow cytometric or impedance methods, may use myeloperoxidase staining for granulocytes, differential may be performed by automated or manual methods
Specimen requirements	Whole blood: EDTA
Indications	Suspected infection, hematologic disorder, or immune deficiency
Reference range	Table 164-20
Interpretation	• Results can vary with time of day, hormonal status, ethnicity (e.g., lower neutrophil counts in persons of African descent) • With infection, total white blood cell (leukocyte) count often elevated, but may be normal or low • Predominance of neutrophils with left shift (immature myeloid precursors) suggests bacterial infection or sepsis but nonspecific; also seen with physical or emotional stress, growth factor treatment • Predominance of lymphocytes and/or monocytes suggests viral or atypical bacterial infection • Eosinophilia suggests allergy, drug effect, or invasive parasitic infection • Abnormal cells suggest leukemia or myelodysplastic syndrome but can also be seen after growth factor treatment • Low counts suggest marrow suppression due to infection, medication, autoimmunity, toxic exposure, metabolic disorder, bone marrow failure, myelodysplastic syndrome, leukemia, or immune deficiency • Generally, automated differentials are more accurate, but a manual differential may be indicated if abnormal or immature cells are present
Related tests	Manual differential, peripheral smear, lymphocyte subsets
Interfering substances	Clotted or hemolyzed sample

EDTA, Ethylenediaminetetraacetic acid; *WBC,* white blood cell.

Lymphocyte Subsets

Summary points	• B, T, and NK cell subsets used to diagnose and characterize immunodeficiency along with other lymphocyte function testing
Methodology	Flow cytometry
Specimen requirements	Whole blood: EDTA or heparin
Indications	Suspected or known immune deficiency; monitor status of HIV disease or immunomodulatory/immunosuppressive therapy
Reference range	Table 164-21
Interpretation	• Absolute declines in lymphocyte subsets can aid diagnosis and characterization of immune deficiencies: primarily B cell, T cell, or combined • T and B cell subsets may decline with immunomodulatory or immunosuppressive therapy • Absolute CD4 counts—monitored in patients with HIV; may define therapy thresholds or risks for specific pathogens • Results may vary with diurnal rhythm
Related tests	Complete blood count, lymphocyte mitogen testing, lymphocyte antigen response testing, antigen-specific IgG/IgM titers after vaccination, PPD testing for delayed type of hypersensitivity response
Interfering substances	Hemolyzed sample, lipemia

EDTA, Ethylenediaminetetraacetic acid; *HIV,* human immunodeficiency virus; *IgG,* immunoglobulin G; *IgM,* immunoglobulin M; *NK,* natural killer; *PPD,* purified protein derivative.

Immunoglobulin A

Summary points	• Important component of mucosal immunity—dimeric form in mucosal secretions, monomeric form in serum • IgA deficiency may occur asymptomatically and may or may not confer increased infection risk • Elevated levels may be seen in monoclonal gammopathies or in setting of chronic inflammation or infection (liver disease, collagen vascular disease, autoimmune disease, chronic infections) leading to polyclonal gammopathy
Methodology	Nephelometry
Specimen requirements	Plain or serum separator tube
Indications	Suspected immune deficiency (recurrent infections), monoclonal gammopathy, isolated IgA deficiency, anaphylactic transfusion reaction to plasma
Reference range	Table 164-22
Interpretation	• Decreased with immune deficiency, celiac disease, some autoimmune diseases, medications, protein loss (nephrotic syndrome, protein-losing enteropathy), non-IgA monoclonal gammopathy • Increased in polyclonal hypergammaglobulinemia, monoclonal gammopathies, infections (tuberculosis, sepsis), chronic liver disease, collagen vascular disease, autoimmune disease, IgA nephropathy • Reference intervals may vary with methodology and patient ethnicity
Related tests	IgG, IgM, serum protein electrophoresis with immunofixation
Interfering substances	Lipemia, other causes of severe specimen turbidity, microbial contamination
Reference	Woof JM, Kerr MA: The function of immunoglobulin A in immunity, *J Pathol* 208:270, 2006.

IgA, Immunoglobulin A; *IgG,* immunoglobulin G; *IgM,* immunoglobulin M.

Immunoglobulin E

Summary points	• Important in immune response to deep parasitic (nematode) infections • Important mediator of allergic response; level often elevated in patients with bronchial asthma or atopic dermatitis
Methodology	Nephelometry, immunoassay
Specimen requirements	Plain or serum separator tube
Indications	Suspected allergic disease; monitoring allergic bronchopulmonary aspergillosis
Reference range	Table 164-23
Interpretation	• Low levels in hypogammaglobulinemia and selective IgE deficiency • Elevated levels in allergic diseases, deep parasitic infections, malignancy, drug allergy, immune deficiency, some infections and inflammatory disorders; rarely monoclonal IgE gammopathies • IgE measurement has limited value in diagnosing atopy given large overlap between atopic and nonatopic individuals • Normal levels do not exclude allergy
Related tests	IgA, IgG
Interfering substances	Lipemia, other causes of extreme turbidity, microbial contamination
References	Hamilton RG, Adkinson NF Jr: Clinical laboratory assessment of IgE-dependent hypersensitivity, *J Allergy Clin Immunol* 111:S687, 2003. Bacharier LB, Geha RS: Regulation of IgE synthesis: The molecular basis and implications for clinical modulation, *Allergy Asthma Proc* 20(1):1, 1999.

IgA, Immunoglobulin A; *IgE,* immunoglobulin E; *IgG,* immunoglobulin G.

Immunoglobulin G

Summary points	• Largest fraction of serum immunoglobulins; important component of secondary humoral immunity • Elevation seen in monoclonal gammopathies and many polyclonal infectious or inflammatory conditions
Methodology	Nephelometry
Specimen requirements	Plain or serum separator tube
Indications	Suspected immune deficiency (primary or secondary) or monoclonal gammopathy, assess response to immunization or recent or previous infection when antigen-specific IgM and IgG are tested
Reference range	Table 164-24
Interpretation	• Polyclonal elevations seen in hypergammaglobulinemia, chronic liver disease, collagen vascular diseases, autoimmune diseases, some infections • Monoclonal elevations seen in monoclonal gammopathies (plasma cell dyscrasias); confirmed by serum protein electrophoresis with immunofixation • Decreased in immune deficiencies, hypogammaglobulinemia, states of protein loss (protein-losing enteropathy, nephrotic syndrome), some malignancies, medications • Normal IgG levels do not exclude humoral immunodeficiency—further functional studies (assessment of antibody response post vaccine administration) and/or IgG subclasses may be required if high degree of clinical suspicion • Reference intervals may vary with methodology and patient ethnicity
Related tests	IgM, IgA, lymphocyte subsets, serum protein electrophoresis with immunofixation
Interfering substances	Lipemia, other causes of severe turbidity, microbial contamination

IgA, Immunoglobulin A; *IgG,* immunoglobulin G; *IgM,* immunoglobulin M.

Immunoglobulin G Subclasses

Summary points	• IgG subclass deficiencies are uncommon but may be associated with recurrent bacterial infections • Total serum IgG may be normal, even with a subclass deficiency
Methodology	Nephelometry
Specimen requirements	Plain or serum separator tube
Indications	Suspected humoral or combined immune deficiency with normal total serum IgG levels, recurrent respiratory or sinus infections. Testing IgG subclasses has a limited role for assessment of antibody-mediated immune function in patients with recurrent sinusitis and respiratory infections
Reference range	Table 164-25
Interpretation	• Decreased levels in hypogammaglobulinemia • Most frequent abnormality: IgG2 deficiency or combined IgG2-IgG4 deficiency. IgG2 deficiency may be associated with IgA deficiency in patients with chronic respiratory infection • Decreased IgG3 levels may be seen in primary immunodeficiencies (Wiskott-Aldrich syndrome) and type 1 diabetes mellitus • 70% of serum IgG is IgG1—selective IgG1 deficiency is rare • Significance of decreased IgG4 in absence of IgG2 deficiency uncertain
Related tests	IgG, IgM, IgA
Interfering substances	Lipemia, other causes of severe turbidity, microbial contamination
Reference	Maguire G: Are there any clinical indications for measuring IgG subclasses? *Ann Clin Biochem* 39:374, 2002.

IgA, Immunoglobulin A; *IgG,* immunoglobulin G; *IgM,* immunoglobulin M.

Immunoglobulin M

Summary points	• Important component of adaptive humoral immune response as initial antibody type produced after antigen exposure • Measurement of antigen-specific IgM and IgG can be useful in the diagnosis of recent or previous infection • Most common monoclonal immunoglobulin subtype elevated in Waldenström macroglobulinemia; associated with hyperviscosity syndrome
Methodology	Nephelometry
Specimen requirements	Plain or serum separator tube
Indications	Suspected immune deficiency, monoclonal gammopathy, assess response to immunization or recent or previous infection when antigen-specific IgM and IgG are tested
Reference range	Table 164-26
Interpretation	• Elevated in polyclonal hypergammaglobulinemia, chronic liver disease, collagen vascular disease, autoimmune disease, some infections, some immune deficiencies, monoclonal gammopathy (lymphoplasmacytic lymphoma and Waldenström macroglobulinemia), cryoglobulinemia • Decreased in immune deficiencies, hypogammaglobulinemia, chronic protein loss (protein-losing enteropathy, malnutrition), some malignancies • Reference intervals may vary with methodology and patient ethnicity
Related tests	IgG, IgA, lymphocyte subsets, serum protein electrophoresis with immunofixation
Interfering substances	Lipemia, other causes of severe turbidity, microbial contamination

IgA, Immunoglobulin A; *IgG,* immunoglobulin G; *IgM,* immunoglobulin M.

Immunoglobulin Light Chains

Summary points	• Measurement of free light chains is done for diagnosis and monitoring of amyloid, nonsecretory myeloma, and light chain myeloma • Kappa/lambda ratio is critical—excess of kappa versus lambda or excess of lambda versus kappa light chains is consistent with a plasma cell dyscrasia
Methodology	Nephelometry
Specimen requirements	Plain or serum separator tube
Indications	Suspected monoclonal gammopathy, amyloidosis, other plasma cell dyscrasia
Reference range	Table 164-27
Interpretation	Elevated free light chain with either kappa or lambda light chain restriction consistent with amyloidosis or another plasma cell dyscrasia
Related tests	Urine free light chains, urine protein electrophoresis with immunofixation, serum protein electrophoresis with immunofixation, serum immunoglobulin levels (IgG, IgA, IgM)
Interfering substances	Lipemia, other causes of severe turbidity, microbial contamination
Comments	May be more sensitive than serum protein electrophoresis with immunofixation for diagnosis of light chain disease

IgA, Immunoglobulin A; *IgG,* immunoglobulin G; *IgM,* immunoglobulin M.

Complement Fractions C3 and C4

Summary points	• Used to measure complement activation or deficiency • C3 and C4, measured together, examine both classical and alternative complement pathways
Methodology	Nephelometry, quantitative immunoturbidimetric, radioimmunodiffusion, electroimmunodiffusion
Specimen requirements	Plain or serum separator tube
Indications	Measure activity in collagen vascular diseases (systemic lupus erythematosus), complement deficiency, immune complex disease, glomerulonephritis, hereditary angioedema
Reference range	Table 164-28
Interpretation	• Reduced C4 with or without reduced C3 implies classical pathway activation as seen in lupus, immune complex disease, hereditary angioedema due to C1 inhibitor deficiency, chronic liver disease • Reduced C3 with normal C4 implies activation by the alternative pathway (e.g., sepsis) • Elevated C3 and/or C4 implies an acute phase response • Primary deficiency is rare and requires functional assay
Related tests	Total complement CH50, C1q inhibitor
Interfering substances	Lipemia, microbial contamination
Reference	Wen L, Atkinson JP, Giclas PC: Clinical and laboratory evaluation of complement deficiency, *J Allergy Clin Immunol* 113:585, 2004.

Platelet Count and Mean Platelet Volume

Summary points	• Used to assess integrity of hematopoietic and hemostatic systems
Methodology	Automated hematology analyzer—flow cytometric or impedance methods
Specimen requirements	Whole blood: EDTA
Indications	Suspected thrombocytopenia or thrombocytosis
Reference range	Table 164-29
Interpretation*	• Thrombocytopenia • Primary marrow process: infiltration by tumor or fibrosis, bone marrow failure, marrow suppression (drugs, toxins, infections), myelodysplasia • Secondary consumptive or destructive process: immunologic destruction, hypersplenism, microangiopathy, disseminated intravascular coagulopathy • Thrombocytosis • Primary: essential thrombocythemia • Secondary: acute phase reactant, splenectomy, iron deficiency • MPV may increase in destructive processes when larger, immature platelets prevail • MPV elevated in hereditary macrothrombocytopenia (Bernard-Soulier syndrome, MYH9 disorders) and ITP, low in Wiskott-Aldrich syndrome
Related tests	Peripheral smear, complete blood count, platelet aggregometry
Interfering substances	Clotted or hemolyzed sample; difficult or prolonged collections may activate platelets and artifactually decrease the count

EDTA, Ethylenediaminetetraacetic acid; *ITP,* immune thrombocytopenia purpura; *MPV,* mean platelet volume.
*Platelet count may also be estimated by peripheral smear review (count platelets in 5 fields using a 100× oil immersion lens, take the average count, and multiply by 15,000) or manually counted using phase contrast microscopy and a hemocytometer. Automated methods using a hematology analyzer are usually more accurate and preferred.

Immature Platelet Fraction

Summary points	• Similar to reticulated platelet count by flow cytometry, but available on automated hematology analyzers • Analogous to reticulocyte count for erythropoiesis, IPF assesses rate of thrombopoiesis, can help distinguish decreased marrow production versus peripheral destruction as likely cause of thrombocytopenia
Methodology	Automated hematology analyzer—flow cytometric method using light scatter and fluorescence dyes that stain ribonucleic acid (RNA)
Specimen requirements	Whole blood: EDTA
Indications	Aid in differential diagnosis of thrombocytopenia, assess marrow response after marrow injury, chemotherapy, bone marrow transplant
Reference range	Table 164-30
Interpretation	• Increased with increased platelet production as seen in thrombocytopenia due to peripheral destruction (TTP) (assuming normally functioning marrow) • Rise in IPF occurs with marrow engraftment post transplant; precedes a rise in platelet count by a couple of days • Normal or decreased with impaired thrombopoiesis (bone marrow failure)
Related tests	Platelet count, mean platelet volume, complete blood count
Interfering substances	Clotted or hemolyzed specimen
Reference	Briggs C: Quality counts: New parameters in blood cell counting, *Int J Lab Hematol* 31(3):277, 2009.

EDTA, Ethylenediaminetetraacetic acid; *IPF,* immature platelet fraction; *RNA,* ribonucleic acid; *TTP,* thrombotic thrombocytopenic purpura.

Coagulation Screening Tests (PT, aPTT, Fibrinogen)

Summary points	• PT, aPTT used to screen for coagulation factor deficiency and monitor anticoagulation; fibrinogen detects hypofibrinogenemia, dysfibrinogenemia • PT elevated with deficiencies of extrinsic and common pathway factors (PT expressed as INR when used to monitor oral anticoagulant therapy) • aPTT elevated with deficiencies of intrinsic and common pathway factors and inhibitors (heparin, lupus anticoagulant, specific factor inhibitors)
Methodology	Clot detection
Specimen requirements	Citrate
Indications	Suspected coagulation factor deficiency, monitor anticoagulation
Reference range	Table 164-31
Interpretation	• Reference ranges dependent on reagents and instrumentation, requiring laboratory-specific and population-specific ascertainment (e.g., aPTT is normally prolonged during neonatal period) • PT and aPTT vary in their sensitivity to deficiency of individual coagulation factors—PT tends to be least sensitive to FII, aPTT to FIX • Normal aPTT does not exclude mild but clinically significant factor deficiency (especially hemophilia B and von Willebrand disease) • Prolonged PT suggests deficiency of one or more factors (fibrinogen, II, V, VII, X) or presence of a coagulation inhibitor • Prolonged aPTT suggests deficiency of one or more factors (fibrinogen, II, V, VIII, IX, X, XI, or other contact pathway factors) or presence of inhibitor such as lupus anticoagulant or heparin (consider heparin contamination in specimen drawn from a heparinized line) • Prolonged PT and aPTT suggests vitamin K deficiency, liver disease, disseminated intravascular coagulation, common pathway factor deficiency • Isolated prolonged PT (normal aPTT) suggests FVII deficiency • Shortening of aPTT may reflect elevated FVIII level (caused by inflammation) • Spurious prolongation of tests with polycythemia, partially filled collection tube, prolonged storage or warming, clotted specimen
Related tests	Coagulation factor levels (fibrinogen, factors II, V, VII, VIII, IX, X, XI, other contact pathway factors), lupus anticoagulant, mixing studies

aPTT, Activated partial thromboplastin time; *FII,* factor II; *FIX,* factor IX; *FVII,* factor VII; *FVIII,* factor VIII; *INR,* international normalized ratio; *PT,* prothrombin time.

Coagulation Factor Levels (Fibrinogen, II, V, VII, VIII, von Willebrand Factor, IX, X, XI, Contact Pathway Factors)

Summary points	• Choice of which specific factor(s) to measure driven by clinical scenario and screening test results (e.g., isolated prolonged PT suggests FVII deficiency, isolated preoperative aPTT suggests measurement of at least FVIII, FIX, and FXI, to assess bleeding risk) • Low von Willebrand factor may not result in abnormal screening test results
Methodology	Clot detection
Specimen requirements	Citrate
Indications	Suspected coagulation factor deficiency, especially as suggested by prolonged coagulation screening test and subsequent mixing study that corrects, assessment of risk factors for thrombosis (e.g., high FVIII), monitoring of factor replacement therapy in patients with coagulopathy
Reference range	Table 164-31
Interpretation	• No definitive threshold for what constitutes hemostatically adequate factor level, but criteria for diagnosing mild factor deficiency often set at 40%-50% • Fibrinogen, FVIII, and von Willebrand factor are acute phase reactants • Factor deficiency may be due to reduced production (hereditary factor deficiency, liver disease, vitamin K deficiency), increased consumption (disseminated intravascular coagulation), or specific inhibitor (FVIII) • Acquired deficiency of multiple factors occurs with liver disease, vitamin K deficiency (including vitamin K–antagonist therapy or toxicity), disseminated intravascular coagulation—FV, FVII, and FVIII may aid in distinguishing between these • Rare inherited combined factor deficiencies exist (combined FV/FVIII, vitamin K–dependent factors) • With exception of FXI, contact factor deficiencies (FXII, high-molecular-weight kininogen, prekallikrein) may cause prolonged aPTT but are not associated with increased bleeding risk • Vitamin K–dependent and contact factors are physiologically low in early infancy • FV and FVIII are particularly labile, with potential for spuriously low levels—carefully consider abnormally low levels in clinical and laboratory context and assess need for repeat/confirmatory testing
Related tests	Specific factor inhibitor testing, lupus anticoagulant, mixing studies

aPTT, Activated partial thromboplastin time; *FIX,* factor IX; *FV,* factor V; *FVII,* factor VII; *FVIII,* factor VIII; *FXI,* factor XI; *FXII,* factor XII; *PT,* prothrombin time.

Natural Anticoagulants (Antithrombin, Protein C, Protein S, Tissue Factor Pathway Inhibitor)

Summary points	• Severe deficiency associated with severe thrombotic complications or lethality • Acquired deficiencies more common than inherited • Therapeutic repletion may be indicated in some deficiency states
Methodology	Chromogenic (functional) or immunoassay (antigenic)
Specimen requirements	Citrate
Indications	Assessment of thrombotic risk, diagnosis of severe anticoagulant deficiency states, anticoagulant therapy monitoring (antithrombin status with heparin therapy), assessment of repletion need with concentrate (AT, PC)
Reference range	Tables 164-32 and 164-33
Interpretation	• Levels lower in early infancy and may be reduced in acute thrombosis, consumptive coagulopathy, liver disease • Estrogen, heparin, and asparaginase therapy, nephrotic syndrome associated with decreased AT • PC, PS vitamin K dependent—levels reduced with deficiency and vitamin K–antagonist exposure • PS decreased in setting of inflammation, coexisting activated PC resistance (factor V Leiden), pregnancy, estrogen therapy, sickle cell anemia, nephrotic syndrome • No definitive threshold for what levels constitute adequate levels protective against thrombosis, but levels below approximately 70% often considered abnormal
Related tests	Thrombophilia evaluation, anticoagulation monitoring tests
Interfering substances	Hemolyzed sample or lipemia

AT, Antithrombin; *PC,* protein C; *PS,* protein S.

D-dimer

Summary points	• Fibrin degradation byproduct of fibrinolytic process after cross-linking by FXIII • Used as biomarker in thrombosis, disseminated intravascular coagulation • Varied assay methods without clear standardization—reference values specific to method and population critical to interpretation
Methodology	Immunoassay
Specimen requirements	Citrate or EDTA
Indications	Assessment of possible venous thromboembolism, risk stratification for recurrent thrombosis, evaluation of disseminated intravascular coagulation
Reference range	Table 164-34
Interpretation	• Elevated with recent fibrin formation and subsequent fibrinolysis (assuming normal fibrinolytic function) • Elevated with inflammation, malignancy, surgery, recent trauma, bleeding, liver disease, pregnancy • Varied assay methods without clear standardization—reference values specific to method and population critical to interpretation
Related tests	Thrombophilia evaluation, anticoagulation monitoring tests
Interfering substances	Hemolyzed sample or lipemia
Reference	Adam SS, Key NS, Greenberg CS: D-dimer antigen: Current concepts and future prospects, *Blood* 113:2878, 2009.

EDTA, Ethylenediaminetetraacetic acid; *FXIII,* factor XIII.

PFA-100

Summary points	• Widely available method measuring time to platelet plug formation under high shear and in presence of platelet agonists (epinephrine and ADP) • Suboptimal sensitivity and specificity for platelet function disorders and von Willebrand disease
Methodology	Automated aspiration of whole blood
Specimen requirements	Citrate
Indications	Assessment of primary hemostasis
Reference range	Table 164-35
Interpretation	• Determination of site-specific reference ranges recommended—longer closure times have been reported • Prolonged closure times with more severe von Willebrand disease and platelet dysfunction but also with anemia, thrombocytopenia, and antiplatelet therapy • Specimen agitation and delayed time to assay may give spurious results
Related tests	Platelet aggregometry, von Willebrand disease testing
Interfering substances	Antiplatelet therapy and other drugs

ADP, Adenosine diphosphate.

‡No significant differences between males and females; range derived from combined data.
§Transferrin saturation calculated from iron (µmol/L)/total iron-binding capacity. Transferrin, transferrin saturation, and total iron-binding capacity results may be misleading in patients receiving iron therapy. Note that the lower reference limits for serum iron and transferrin saturation in this study are below the limits used to define acceptable levels for nutritional health for these two analytes (see O'Neal RM, Johnson OC, Schaefer AE: Guidelines for the classification and interpretation of group blood and urine data collected as part of the National Nutritional Survey, *Pediatr Res* 4:103, 1970).

Table 164-13 Erythropoietin Reference Values in Infants and Children

SERUM ERYTHROPOIETIN LEVELS IN TERM INFANTS DURING THE FIRST YEAR OF LIFE*

Days After Birth	Erythropoietin (Milli–International Unit/mL)	Hemoglobin (g/dL)	RBC (×106/µL)
0-6	33.0 ± 31.4 (11)	15.6 ± 2.2 (11)	4.51 ± 0.74 (11)
7-50	11.7 ± 3.6 (7)	12.8 ± 1.1 (5)	3.92 ± 0.35 (5)
51-100	21.1 ± 5.5 (13)	11.4 ± 1.0 (10)	4.09 ± 0.51 (10)
101-150	15.1 ± 3.9 (5)	11.2 ± 1.1 (3)	4.21 ± 0.31 (3)
151-200	17.8 ± 6.3 (6)	—	—
>201	23.1 ± 9.7 (10)	11.8 ± 0.8 (9)	4.57 ± 0.24 (9)

From Yamashita H, Kukita J, Ohga S, et al: Serum erythropoietin levels in term and preterm infants during the first year of life, *Am J Pediatr Hematol Oncol* 16:213, 1994.
*Values are expressed as means ± SD; parentheses enclose number of specimens. Patients were not transfused and weighed 2500 g or more.

PLASMA ERYTHROPOIETIN REFERENCE RANGES IN CHILDREN†

Age (yr)	Number	Male Subjects	Number	Female Subjects
1-3	122	1.7-17.9	97	2.1-15.9
4-6	89	3.5-21.9	76	2.9-8.5
7-9	79	1.0-13.5	80	2.1-8.2
10-12	98	1.0-14.0	90	1.1-9.1
13-15	100	2.2-14.4	148	3.8-20.5
16-18	66	1.5-15.2	77	2.0-14.2

From Krafte-Jacobs B, Williams J, Soldin SJ: Plasma erythropoietin reference ranges in children, *J Pediatr* 126:601, 1995.
†Values are expressed in milli–International Unit/mL. Data were obtained from a total of 1122 hospitalized and outpatient children ages 1 to 18 years, using a commercially available enzyme-linked immunosorbent assay methodology. Values are 2.5th to 97.5th percentiles.

Table 164-14 Folate Reference Values

RBC FOLATE THRESHOLDS*

<305 nmol/L (140 ng/mL)	Folate deficiency
305-340 nmol/L	Subclinical deficiency (with elevated homocysteine)
>900 nmol/L (400 ng/mL)	Reduced risk for neural tube defect in pregnancy

PLASMA LEVELS OF FOLIC ACID IN CHILDREN†

Age	Males (nmol/L)	Females (nmol/L)
0-1 yr	16.3-50.8	14.3-51.5
2-3 yr	5.7-34.0	3.9-35.6
4-6 yr	1.1-29.4	6.1-31.9
7-9 yr	5.2-27.0	5.4-30.4
10-12 yr	3.4-24.5	2.3-23.1
13-18 yr	2.7-19.9	2.7-16.3

*Data from Green R: Indicators for assessing folate and vitamin B-12 status and for monitoring the efficacy of intervention strategies, *Am J Clin Nutr* 94:666S, 2011.
†From Hicks JM, Cook J, Godwin ID, et al: Vitamin B12 and folate: Pediatric reference ranges, *Arch Pathol Lab Med* 117:704, 1993. Data were collected from hospitalized patients; 2.5th to 97.5th percentile values adapted from the Hoffman technique. Specimens from more than 100 patients in each age-group were analyzed by radioimmunoassay.

Table 164-15 Plasma Levels of Vitamin B_{12} in Children

Age	Males (pmol/L)	Females (pmol/L)
0-1 yr	216-891	168-1117
2-3 yr	195-897	307-892

Table 164-18 Red Blood Cell Enzyme Activity in Adults and Term Infants*

Enzyme	Adults ($n = 20$)	Infants ($n = 10$)
Hexokinase	12.9 ± 2.1	34.0 ± 6.0
Phosphoglucose isomerase	406 ± 37	560 ± 112
Phosphofructokinase	148 ± 24.5	84.5 ± 24
Aldolase	24.5 ± 3.7	42.0 ± 10.0
Glyceraldehyde-3-phosphate dehydrogenase	885 ± 127	884 ± 245
Triosephosphate isomerase	26,323 ± 3240	29,111 ± 4100
Phosphoglycerate kinase	2795 ± 144	3926 ± 528
Phosphoglycerate mutase	751 ± 99	1049 ± 160
Enolase	252 ± 54	517 ± 121
Pyruvate kinase	179 ± 16	256 ± 50
Lactic dehydrogenase	2033 ± 287	2756 ± 425
Glucose-6-phosphate dehydrogenase	215 ± 18	328 ± 40

Reproduced with permission from Oski FA: Red cell metabolism in the newborn infant. V. Glycolytic intermediates and glycolytic enzymes, *Pediatrics* 44:84, 1969.
*Infant samples were obtained from newborns weighing more than 2800 g whose gestational age was 39 weeks or greater. Blood was drawn within 24 hours of birth. All the newborns were clinically healthy. Adult samples were obtained from healthy, normal volunteers. Units per 100 mL of red blood cells.

Table 164-19 Red Cell Glycolytic Intermediate Metabolites in Normal Adults, Term Infants, and Premature Infants*

Metabolite	Normal Adults ($n = 10$)	Term Infants ($n = 10$)	Premature Infants ($n = 11$)
Glucose-6-phosphate	24.8 ± 9.8	45.2 ± 8.7	66.8 ± 34.8
Fructose-6-phosphate	5.4 ± 1.0	9.9 ± 2.3	20.5 ± 8.9
Fructose-1,6-diphosphate	4.6 ± 1.0	3.8 ± 0.7	3.6 ± 0.8
Dihydroxyacetone phosphate	4.9 ± 3.5	11.9 ± 5.0	18.6 ± 10.7
Glyceraldehyde-3-phosphate	2.6 ± 0.7	1.9 ± 1.6	6.5 ± 3.2
3-Phosphoglycerate	61.6 ± 12.4	58.2 ± 14.4	47.5 ± 14.2
2-Phosphoglycerate	4.3 ± 1.8	4.9 ± 1.6	4.4 ± 2.5
Phosphoenolpyruvate	8.8 ± 2.6	7.6 ± 2.9	7.4 ± 3.0
Pyruvate	73.5 ± 33.1	70.4 ± 32.3	78.4 ± 4.15
2,3-Diphosphoglycerate	4423 ± 1907	3609 ± 800	3152 ± 2133

Reproduced with permission from Oski FA: Red cell metabolism in the newborn infant. V. Glycolytic intermediates and glycolytic enzymes, *Pediatrics* 44:84, 1969; and Beutler E: G6PD deficiency, *Blood* 84:3613, 1994.
Units per 100 mL of red blood cells.
*Premature infants had birth weight below 2200 g and gestational age of less than 37 weeks and were clinically healthy at the time of investigation.

From Dallman PR: Blood-forming tissues. In Rudolph AM, editor: *Pediatrics,* ed 16, New York, 1977, Appleton-Century-Crofts, p 1178.
*Numbers of leukocytes are in thousands per cubic millimeter, ranges are estimates of 95% confidence limits, and percentages refer to differential counts. Neutrophils include band cells at all ages and a small number of metamyelocytes and myelocytes in the first few days of life.
†Normal ranges vary sightly depending on automated analyzer used. The total leukocyte count is used to convert percentage values to absolute counts. Some automated hematology analyzers provide a full or limited differential.

Basophils‡	
Absolute range	3-100/mm^3
Percentage range	0.10%-1.47%

‡Data based on 668 normal individuals ages 5 to 74 years; range reflects 2.5th to 97.5th percentiles; counts obtained using a Hemalog D cytochemical automated counter. From Simmons A, Leaverton P, Elbert G: Normal laboratory values for differential white cell counts established by manual and automated cytochemical methods (Hemalog D™), *J Clin Pathol* 27:55, 1974.
